Human Brain Evolution

HUMAN BRAIN EVOLUTION

Modern evidence concerning brain evolution from comparative studies shows that brain structure, far from being uniform across species, exhibits remarkable variations. This chapter focuses on the evolutionary history of three groups of vertebrates that are of special interest to people: mammals, primates, and humans themselves. The major steps are outlined in the evolution of our large, complex, and extremely useful brains from the smaller, simpler brains of the first mammals, with an emphasis on the neocortex, since this part of the brain is disproportionately large in humans and is critically involved in mental activities and processes that are considered to be distinctly human. We review new evidence about the changes in the internal organization of brains that took place after the human lineage diverged from the lineage leading to our closest relatives, chimpanzees.

THE BRAINS OF EARLY MAMMALS

As early as 340 mya, early reptiles, now most often called "stem amniotes," evolved from amphibians and diverged into two major clades, the sauropsids, which led to present-day reptiles and birds, and the synapsids, which left no survivors other than mammals (Fig. 42.1). We know from the fossil record that early mammals were mainly small, mouse- to cat-sized, and the endocasts of their skulls (Box 42.1) indicate that they had small brains in proportion to their body sizes. In addition, their forebrains were dominated by a large olfactory bulb and a proportionately large expanse of olfactory cortex. In contrast, neocortex was restricted to a small cap on the dorsal surface of the forebrain that failed to extend over the midbrain, as it does in most extant mammals. Thus, olfaction was a very important sense in early mammals, and neocortex was not the dominant structure that it is in most extant mammals. In addition, most early mammals appeared to have been nocturnal with rather poor vision. However, early mammals evolved small bones in the middle ear, the malleus and incus, which together with the stapes transmit oscillations of air pressure to the cochlea of the inner ear. This, and modifications of the cochlea, allowed early mammals to extend their hearing into high frequencies, permitting communication signals that would be undetected by reptilian predators (Allman, 1999). As auditory processing became more important, the inferior colliculus of the auditory midbrain became larger than its visual counterpart, the superior colliculus (Fig. 42.2). As with many extant mammals, touch receptors for facial vibrissae and for the tongue and lips probably provided much of the somatosensory input.

The neocortex of early mammals was perhaps the part of the brain most changed from early ancestors. Neocortex is not, as its name implies, a new part of the brain, as neocortex is homologous to the dorsal cortex of reptiles. Thus, a forebrain structure in early amniotes evolved into neocortex in the sauropsid line leading to mammals and to dorsal cortex in the line leading to modern reptiles and birds (the hyperpallium or wulst in birds). Although it is not known exactly how the dorsal cortex of early amniotes evolved into the neocortex of early mammals, the dorsal cortex of the sauropsid ancestors of mammals is generally thought to resemble the dorsal cortex of present-day reptiles, such as turtles (Fig. 42.3). The dorsal cortex of reptiles consists of a single layer of pyramidal neurons capped by a layer of input axons mixed with dendrites of the pyramidal neurons and a few (10–20 percent) largely inhibitory intrinsic neurons. The fiber layer under the pyramidal cells consists of the axons leaving the pyramidal cells. This type of laminar and cellular organization is also found in medial cortex of reptiles that is homologous to the hippocampal formation of mammals and birds, and the lateral or

BOX 42.1

HOW DO WE LEARN ABOUT BRAIN EVOLUTION?

There are three main ways to learn about how different brains have evolved. First, the fossil record can be studied. Because bones readily fossilize, whereas soft tissues seldom do, we know a lot about the bones of our ancestors, but much less about everything else. Of course one can infer much about some soft tissues, such as muscles, from their effects on bones, and this is true for brains as well. The brains of mammals fill the skull tightly, and thus the skull cavity of fossils (the endocasts) rather closely reflects the size and shape of the brain, and even the locations of major fissures. Much has been learned about the changes in brain size from the fossil record (Jerison, 2007), and we learn more by considering changes in the proportions of brain parts. For example, early primates already differ from most early mammals by having more neocortex in proportion to the rest of the brain, and more neocortex devoted to the temporal lobe where visual processing occurs. This implies a greater emphasis on functions mediated by neocortex and a greater emphasis especially on the processing of visual information.

We can even learn something about the functional organization of the neocortex from fossils. For instance, subdivisions of the body representation in the primary somatosensory cortex are often marked by fissures in the brain, and fissure patterns revealed by endocasts from fossil skulls have been used to suggest specializations of the somatosensory cortex in extinct mammals (Radinsky, 1976). David Van Essen (2007) has proposed that an important factor in the development of brain fissures is the pattern of connections within the developing brain. According to this theory, densely interconnected regions tend to resist separation during brain growth and form bulges (gyri) that limit the separation distance, whereas poorly interconnected regions are free to fold and form fissures (sulci) that would increase the separation distance. Thus, it is because the hand and face regions of the somatosensory cortex are poorly interconnected that a fissure may develop between the two. In a similar manner, the position of the lunate sulcus has been used to indicate the junction of primary with secondary visual cortex in fossil endocasts of hominid skulls (de Sousa et al., 2010). Thus, the locations of brain fissures in fossil endocasts may tell us something about anatomical connections and functional boundaries in the brains of extinct mammals.

Most of what is known about the evolution of brains is based on comparisons of brain organization of different species of present-day (extant) mammals and other vertebrates. As Darwin recognized, each living species represents the living tip of a largely dead branch of an extremely bushy tree of life. By examining other living tips of the tree, we can infer much about the organizations of the brains (and other body parts) of ancestors that occupied the branching points of this tree. Theories of brain evolution, including those of the evolution of the human brain, depend on reconstructing the probable features of the brains of ever more distant relatives. The comparative method depends on (1) examining the brains of suitable ranges of extant species and (2) determining what features they share, and whether these features are shared because they were inherited from a common ancestor or because they evolved separately. The field of cladistics provides guidelines for making such judgments. The choice of species for comparison depends on the question being asked. For example, to deduce what the brains of early mammals were like, one should examine brains from each of the major branches of the mammalian evolutionary tree (Fig. 42.1). In order to learn about early primates, we need to consider the major branches of primate evolution along with mammals that are thought to be closely related to primates such as tree shrews.

Although the brains of some mammals may have retained more primitive characteristics than others, it is unlikely that the brain of any living mammal fully represents an ancestral condition. Brain features need to be evaluated trait by trait in a comparative context, as any particular feature could be primitive (ancestral) or derived (modified). To reconstruct the course of brain evolution, we need to distinguish ancestral and derived characters. We expect modern species to exhibit a mixture of features that have been retained from a range of ancestors from recent-to-ancient, as many features or traits are thought to evolve independently (called mosaic evolution), although features can be linked and evolve together.

A third source of information about brain evolution is based on understanding the mechanisms and modes of brain development and the constraints they impose on evolution. For example, Finlay and Darlington (1995) have presented evidence that brains change in orderly ways, as they get bigger. In general, larger brains have proportionately more neocortex and less brain stem. Finlay and Darlington suggest this is the case because the late-maturing neocortex of large brains grows longer (late makes great). Another difference between large and small brains is that large brains have more neurons and longer connections. The increase in neurons makes it difficult for each neuron in a large brain to maintain the same proportion of connections with other neurons, as do neurons in a small brain, and to maintain the same transmission times over longer axons. Thus, as larger brains evolve, changes in organization are needed to reduce the commitment to connections, especially connections requiring long, thick axons. A deeper understanding of the genetic, developmental, and structural constraints on brain design could allow us to better postulate how brains are likely to change in organization with changes in brain size.

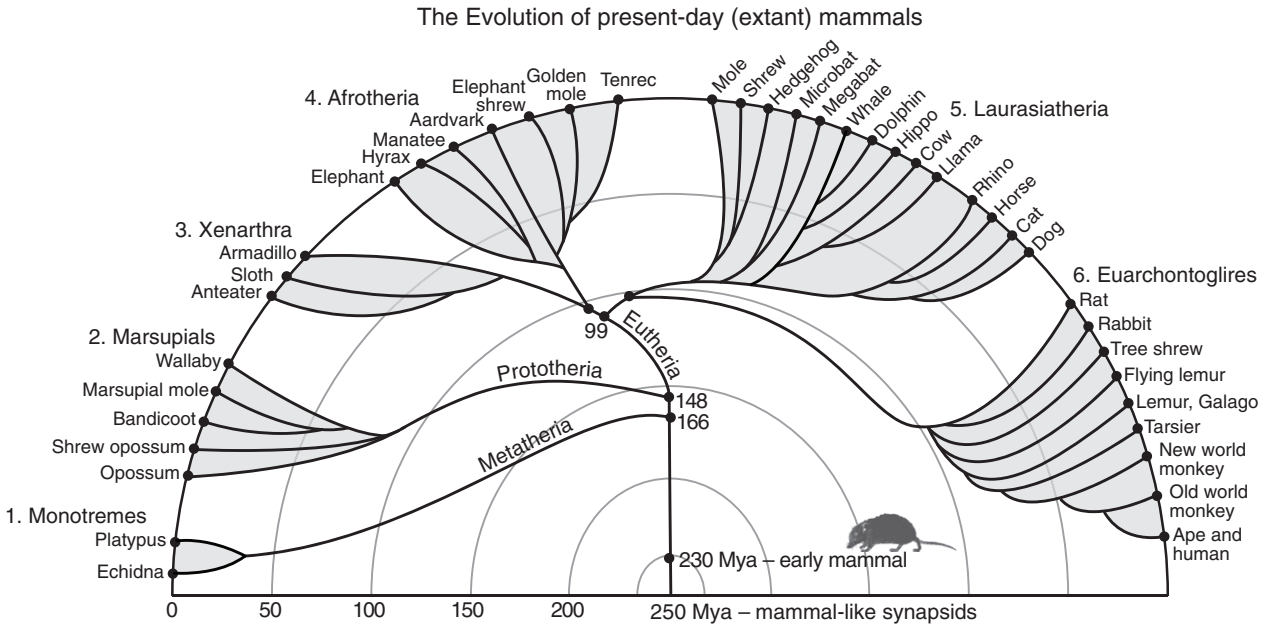

FIGURE 42.1 The phyletic radiation of extant mammals into six major clades or superorders. Most early mammals were shrew-like in appearance. They emerged from mammal-like synapsids about 230 million years ago (mya). Humans and other primates are in the Euarchontoglire superclade. *Based on Murphy, Pevzner, and O'Brien (2004).*

piriform olfactory cortex of mammals, reptiles, and birds (Shepherd, 2011). However, dorsal cortex of mammals evolved new cell layers, to become the familiar six-layered neocortex of mammals. The single layer of pyramidal cells of dorsal cortex was expanded to form the superficial layers 2 and 3, and the deep layers 5 and 6, with each layer specialized for receiving different inputs and providing different outputs, while a middle layer 4 of stellate cells was specialized for receiving fine-grain sensory or other information from the thalamus or other areas of cortex and distributing it to the other layers (Shepherd, 2011). In addition to having the potential to form new kinds of local circuits, the neocortex of early mammals had the potential to be subdivided into any number of functionally different cortical areas that could relate to other areas in various ways, and these cortical areas could be subdivided into sets of repeating modules or columns, providing further computational advantages. As a result, neocortex became a very important part of the brain in some mammals, providing 80 percent of the total brain mass in humans (Azevedo et al., 2009). However, large brains with massive amounts of neocortex came with great costs, including considerable metabolic requirements, and long development times. Larger brains also generate more heat, and are difficult to keep cool (Falk, 1990). In order to have larger amounts of neocortex, a mammal needs to have the potential of a relatively long life and access to high-quality food (Aiello & Wheeler, 1995). Thus, many mammals have small brains and little neocortex with limited computational ability, and likely short lives that are compensated by early maturation, lower metabolic costs, and early reproduction.

Although the neocortex of early mammals was small in comparison to the rest of the brain, it already had several functionally distinct subdivisions. By comparing the organization of neocortex in the brains of members of the six major clades (a clade is any group where all members descended from a common ancestor) of extant mammals (Fig. 42.1), especially those mammals with small brains and relatively little neocortex, we can identify features these brains have in common as a result of sharing an early mammal ancestor. Such a comparative approach leads to several well-supported conclusions (Kaas, 2007a, 2007b, 2011a). First, cortical areas were more similar to each other structurally, and less specialized, than in most extant mammals. While most areas of neocortex had the familiar pattern of six layers of cells, the layers were not markedly different in the types and shapes of intrinsic neurons and pyramidal neurons. Cortical areas were structurally similar, although primary sensory areas were probably already distinguished by having a layer 4 that was more densely packed with small neurons than other cortical areas, and retrosplenial cortex on the medial wall of the cerebral hemisphere was distinguished by having a thin, poorly differentiated layer 4 and a relatively thick layer 2. In general layer 2 was more distinct and layer 1 thicker across cortex than in most extant mammals, reflecting the retention of aspects of dorsal cortex. The structural appearance of neocortex in marsupial opossums (Wong & Kaas, 2009) roughly approximates that expected for early mammals.

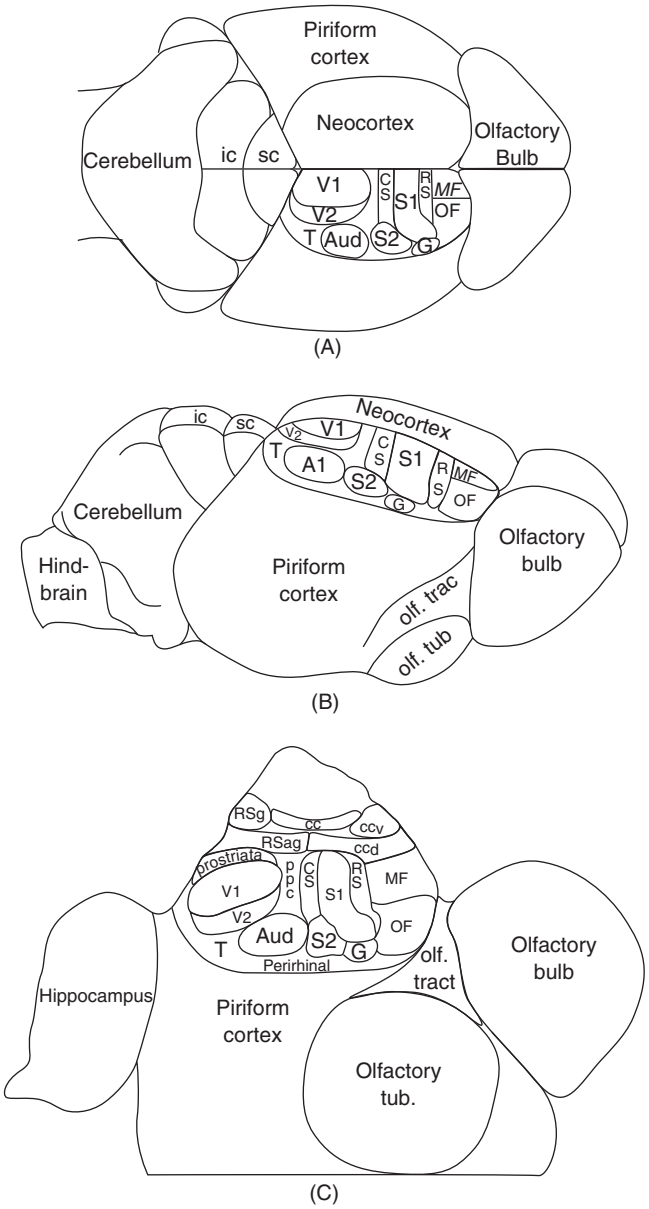

FIGURE 42.2 The inferred organization of neocortex in early mammals. The figure emphasizes the small neocortex in proportion to olfactory piriform cortex and olfactory bulb reflected in the brain endocasts of early mammals. Comparative studies of extant mammals reveal cortical areas that are widespread across mammalian clades, suggesting that they have been retained from early mammalian ancestors. **A.** Dorsal view of the brain with cortical areas indicated. **B**. Lateral view. **C.** View of cortex after it has been separated from the brainstem and unfolded to reveal cortex of the medial wall of the cerebral hemisphere. The hippocampus has been unfolded. Cortical areas include primary and secondary visual areas, V1 and V2, primary and secondary somatosensory areas, S1 and S2, a primary-like auditory core, Aud., caudal and rostral somatosensory belts bordering S1, CS and RS, a gustatory area, G, orbital frontal, OF, and medial frontal, MF, cortex, posterior parietal cortex, PPC, temporal visual cortex, T, dorsal and ventral cingulate cortex, CCd and CCv, and agranular and granular retrosplenial cortex, RSag and RSg, corpus callosum, CC, inferior colliculus, ic, superior colliculus, sc, olfactory tubercle, Olf. Tub., and olfactory tract, Olf. Trac.

We can also conclude that the small cap of neocortex of early mammals was subdivided into a small number of functionally distinct areas, on the order of 10–20, and that these areas have been retained in most lines of descent. From slight regional differences in the laminar appearance of neocortex, early investigators such as Brodmann (1909) surmised that all mammals have functionally significant subdivisions of cortex called areas. Some of these areas are shared by many species (homologous areas retained from a common ancestor), while others are found only in some branches of mammalian evolution. However, it was difficult for Brodmann and other early investigators to reliably identify areas by their differences in histological appearance, especially in the poorly differentiated cortex of most small-brained mammals, but also in the large expanses of rather homogeneous cortex present in large-brained mammals. As a result, areas were often incorrectly delimited within species, and misidentified across species. Fortunately, modern methods of investigation allow many features of cortical biology to be compared in great detail, including patterns of neural connections, ways of representing sensory and other inputs, neuron response properties, and cortical histochemistry. This added information allows cortical areas to be identified within and across species with much more assurance. Nevertheless, many areas remain difficult to identify and delimit with certainty.

When we consider the known distribution of cortical areas in small-brained mammals from the major branches of the mammalian radiation (Fig. 42.1), such as opossums, armadillos, tenrecs, hedgehogs, and even rats (Kaas, 2011a), we find a number of shared areas (Fig. 42.3). Except for a few blind or nearly blind species, such as mole-rats, mammals have a caudally located primary visual area, V1, that is architectonically distinct, has dense inputs from the lateral geniculate nucleus of the visual thalamus, and contains a representation of the contralateral visual hemifield. Other visual areas have been harder to define, but there is widespread evidence across many species for a second visual area, V2, along the lateral border of V1. Thus, it appears that early mammals had a V2, and this V2 has been retained in most present-day mammals. Exceptions are nearly blind mammals, and a few species such as the least shrew that evolved to have extremely small bodies and brains, resulting in the loss of V2 and a few other areas (Catania, Lyon, Mock, & Kaas, 1999). Evidence from comparative studies also supports the conclusion that early mammals also had a visual area along the medial border of V1, a less well-studied area given several names, but commonly called the prostriate area. In addition, one visual area or more was likely located lateral to V2 in temporal cortex of early mammals (T in Fig. 42.2). Because the dorsal cortex of reptiles is predominantly visual in function (Fig. 42.3), one or more visual areas

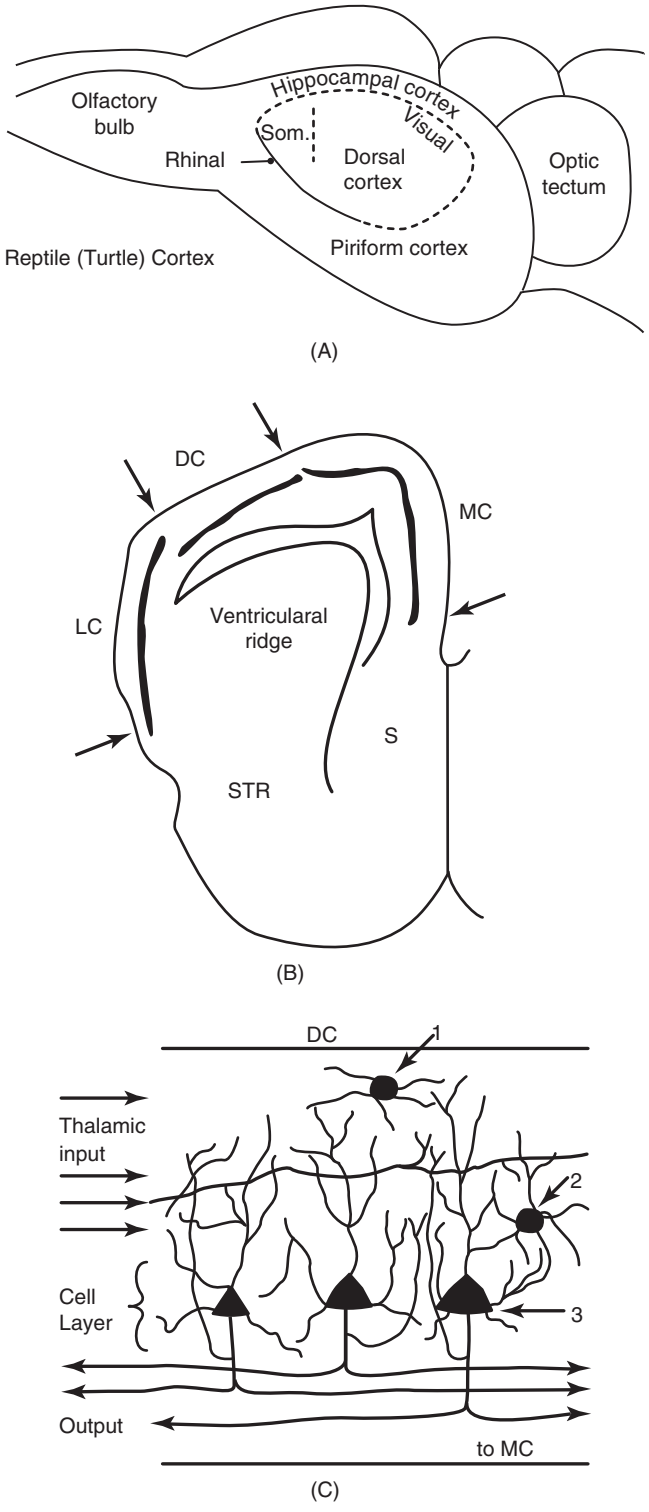

FIGURE 42.3 Dorsal cortex of reptiles. **A.** A dorsolateral view of a turtle brain. The large olfactory bulb provides input to lateral cortex (homologue to piriform cortex of mammals). A slight rhinal dimple is apparent rostrally at the border of dorsal cortex (homologous to neocortex of mammals). Medial or hippocampal cortex (homologous to the hippocampus of mammals) is medial. Most of dorsal cortex receives visual inputs, while a small rostral zone receives somatosensory (som.) inputs. The large optic tectum is part of the midbrain. **B.** A frontal section through the forebrain of a reptile showing the locations of the dorsal cortex (DC), the lateral cortex (LC) and the medial cortex (MC). The solid lines in these cortical areas represent the densely packed pyramidal neurons that form a single cell layer in all three areas. S = septum; STR = striatum. **C.** The cellular structure of dorsal cortex. A densely packed row of pyramidal neurons forms a middle layer. Pyramidal neurons constitute 80 to 90 percent of the neurons in DC. They receive inputs from the visual thalamus as thalamocortical axons stream from lateral to medial in dorsal cortex synapsing on many pyramidal neurons. A few subpial and stellate cells are inhibitory on pyramidal neurons after being activated by pyramidal neuron axons, and input axons. The main branch of pyramidal neuron axon bifurcates with one collateral coursing medially to MC, and the other collateral coursing to the striatum, the visual thalamus, and the optic tectum. Other branches activate other pyramidal neurons and intrinsic neurons. 1. Subpial interneuron. 2. Stellate interneuron. 3. Pyramidal neuron.

likely existed in the dorsal cortex of the synapsid ancestors of mammals.

The organization of auditory cortex has been less studied across a range of mammalian taxa, but a primary or primary-like region has been identified in ventral temporal cortex of all studied mammals (Kaas, 2011b). In many of these mammals, the cortex with primary-like architectonic features includes two or sometimes three different representations of tone frequencies, with one of the representations termed the primary area, A1, and the other, the anterior auditory field among other names. Without further comparative studies, it is uncertain if the primary auditory region of early mammals (Aud) contained a single area, A1, or more. This auditory core area was likely bordered by one or more secondary (belt) auditory fields, but this remains uncertain. Auditory inputs apparently are not represented in dorsal cortex of reptiles and may not have been present in synapsids.

All mammals have several somatosensory areas. A primary area, S1, represents touch on the contralateral half of the body from the tail to the tongue in a mediolateral sequence across anterior parietal cortex. Lateral to S1, a second somatosensory area, S2, has been identified in a wide range of mammals, and the adjoining parietal ventral area, PV, has often been reported, suggesting that S2 and possibly PV (not shown in Fig. 42.2, but located just rostral to S2) were present in early mammals. In addition, narrow bands of cortex along the rostral and caudal borders of S1 with inputs from S1 likely existed, termed here the rostral and caudal somatosensory areas, RS and CS. RS likely had proprioceptive inputs as in area 3a of cats and primates and dysgranular somatosensory cortex of rats. Perhaps surprisingly, early mammals did not have a primary motor area, M1, or any of the premotor areas that characterize primates. This follows from the lack of compelling evidence for an M1 or premotor cortex in marsupials or monotremes, animals that represent early branches of the mammalian radiation. However, inputs from the cerebellum to the anterior thalamus were probably present, and

this motor-related information was distributed to somatosensory cortex, which had motor as well as sensory functions. As dorsal cortex in reptiles appears to have a small region with somatosensory inputs, a region of somatosensory cortex may have been present in the synapsid ancestors of mammals. Finally, there may have been a small region of gustatory cortex, G, located lateral and somewhat rostral to S1 in ancestral mammals, but this is uncertain, as there have been few comparative studies of the representation of taste in the cortex of mammals.

Other cortical areas have been less widely identified in comparative studies, so their presence in early mammals is uncertain. Yet the architectonic features of the granular and agranular retrosplenial areas, RSg and RSa, are distinctive enough to have them be widely identified. There is also reasonably good evidence that early mammals had at least two divisions of cingulate cortex, and two divisions of frontal cortex. Overall, early mammals had a thick neocortex of six layers that was subdivided into as many as 15 or more cortical areas. How this neocortex emerged from the thin, small dorsal cortex with possibly only visual and somatosensory inputs in the ancestors of mammals remains a challenging question (Puelles, 2011).

From this ancestral pattern, a great variety of brain organizations have evolved through alterations in the sizes and numbers of parts, and the connections within and between parts (Kaas, 2007a). Consider, for example, the variations of the primary somatosensory cortex. The duck-billed platypus devotes most of S1 to representing tactile receptors of its highly sensitive bill, and it has added inputs from electroreceptors. The star-nosed mole devotes most of S1 to its long, fleshy nose appendages, rats mostly activate S1 with their facial whiskers, and human S1 has a large representation of the hand, lips, and mouth. In addition, the amount of neocortex varies greatly across species of mammals (Jerison, 2007), and some of this variation is due to differences in numbers of cortical areas present in different groups of mammals (Changizi & Shimojo, 2004; Finlay & Brodsky, 2007; Kaas, 2007a). The number of sensory areas increased independently in several lines of evolution. For example, both cats and monkeys have a large number of visual areas, but the carnivore and primate lines appear to have acquired most of these areas independently rather than from a common ancestor. Thus, many of the visual areas in cats have no homologs in monkeys or humans. A similar situation holds for other regions of the brain. New areas were added, most commonly to sensory and motor regions of cortex rather than to multisensory "association" cortex as once thought. However, sensory areas typically are modulated by other inputs including other sensory and nonsensory inputs. With new cortical areas, new connections between areas and subcortical structures emerged. How new areas evolve remains unclear: they could result from the duplication of existing areas, or by the gradual subdivision of existing areas, or both.

Thus, mammals in various lines of descent evolved new cortical areas and connections, as well as many other specializations of previously existing areas. A long-recognized example of a new brain feature is the corpus callosum, a derived character of placental mammals, having emerged in the ancestors of placentals after they diverged from marsupials. Whereas connections between the two hemispheres are mediated by the anterior commissure in marsupials and monotremes, most of these connections are carried in the shorter, more direct callosal pathway in placental mammals. Primary motor cortex, M1, is another important brain feature that appears to have emerged in early placental mammals after the split from marsupials.

EVOLUTION OF PRIMATE BRAINS

Evolution of Primates

Early primates emerged from small-brained, nocturnal, insect-eating mammals, perhaps as much as 80 million years ago (Martin, 2007), and subsequently branched into two main lineages (Fig. 42.4). One lineage, the strepsirrhines, includes lemurs, lorises, and galagos (collectively, most of the "prosimian" primates). A second lineage, the haplorhines, includes two important daughter branches, one leading to the small, strepsirrhine-like tarsiers, the other leading to the familiar anthropoid primates, which include a New World radiation (the platyrrhines, or New World monkeys) and an Old World radiation (the catarrhines, comprising the Old World monkeys and the ape-human group).

The earliest primates are thought to have been small-bodied, nocturnal visual predators living on insects and small vertebrates, as well as fruit. They adapted to the tropical rainforests by emphasizing vision and visually guided reaching and grasping. This involved having larger, forward-facing eyes, opposable big toes and thumbs, and digits tipped with nails rather than claws. These primates produced the largely nocturnal strepsirrhine radiation with its varied forms, including some species now living in Madagascar that have become diurnal. The haplorhine primates emerged about 60 million years ago in association with a shift from nocturnal to diurnal life, together with an increased emphasis on fruit eating (Ross, 1996). With the shift to diurnal activity came reduced dependence on olfaction, enhancement of the visual system, enlarged body size, and sometimes a more gregarious mode of life. Specifically, the olfactory apparatus was reduced in size, and the eyes enlarged and brought close together. Early haplorhines evolved a fovea, a specialized region of the retina filled with small photoreceptors and devoid of blood vessels that enhances central

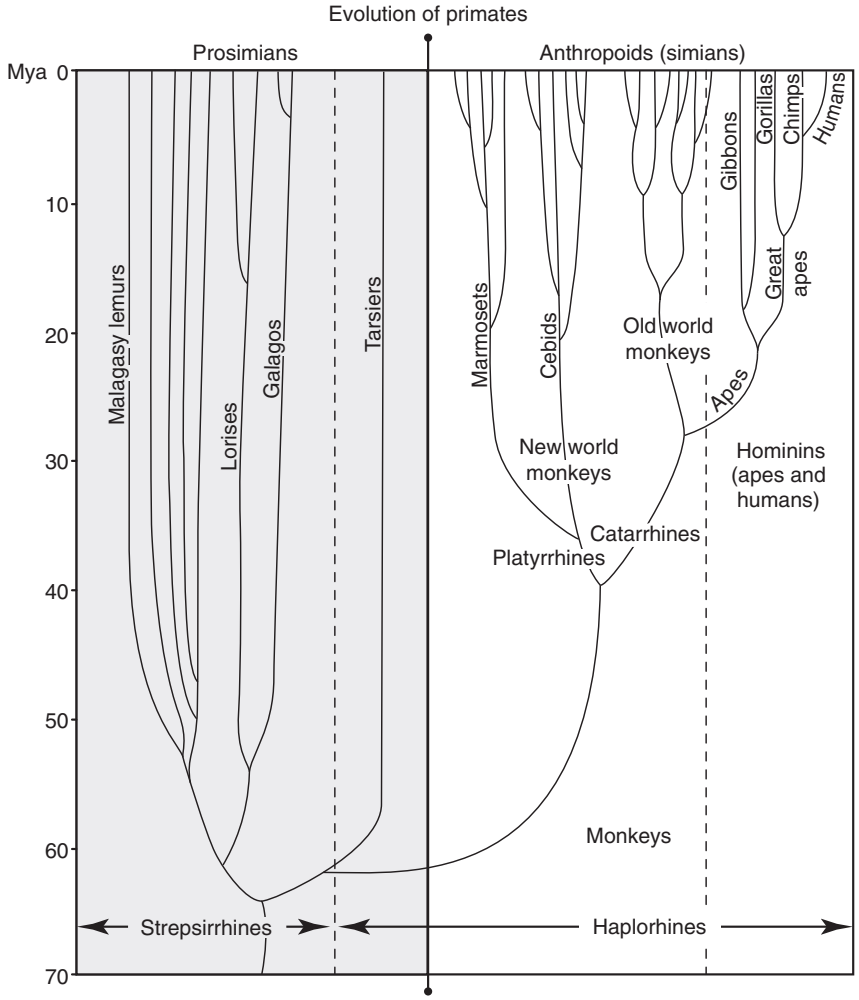

FIGURE 42.4 The evolution and classification of primates. Tarsiers are generally considered to be prosimians, but they are related more closely to anthropoids, so they are recognized as haplorhine primates. Despite the ancient split of strepsirrhines and haplorhines, they share many brain features that are unique to primates. Tree shrews and flying lemurs are thought to be close relatives of primates, and together with them constitute the superorder Archonta. See text.

visual acuity. The reflecting surface at the back of the eye (*tapetum lucidum*), an adaptation to nocturnal vision present in strepsirrhines and many other nocturnal mammals, was lost. Anthropoids underwent further specializations, modifying cone morphology, increasing the proportion of cones to rods, and filling the fovea with cones to the near exclusion of rods. These adaptations enabled anthropoids to achieve a high degree of color discrimination. Nevertheless, whereas humans and other Old World anthropoid primates have three types of retinal cones, ancestral anthropoids probably possessed two types of cones, similar to most modern strepsirrhines and New World monkeys. A third cone type, enabling full trichromatic vision, appears to have evolved independently in the ancestors of Old World anthropoids and in several New World monkey groups. The enhancements of color vision in the anthropoids are plausibly adaptations for distinguishing ripe, edible fruits. The shift to diurnal activity was also marked by larger social groupings, which may offer enhanced protection from predation. These changes were accompanied by increased brain size, including increases in the temporal lobe visual region, and in regions of the parietal and frontal cortex mediating motor control and social interactions.

The ancestors of present-day tarsiers evidently abandoned the diurnal niche to become nocturnal visual predators again. Tarsiers retain a fovea, but they have a rod-dominated retina and their enormous eyes are sensitive at low light levels without the aid of a reflecting tapetum. The primary visual cortex became very large relative to the rest of the brain and is extremely well differentiated, with a multiplicity of layers and sublayers (Wong, Collins, & Kass, 2010). Tarsiers became such extremely specialized visual predators that they eat no plant food. Other haplorhines (anthropoids) remained diurnal and spread to many niches, including those outside the rainforest and niches

based more on eating leaves as well as fruits. Some increased considerably in body size. Later anthropoids were able to process hard, husked fruits with their hands and teeth. Some early anthropoids managed to reach South America from Africa, apparently by rafting, to form the New World monkey radiation. All modern anthropoids are diurnal with the exception of owl monkeys, a New World monkey group that has (like tarsiers) become secondarily nocturnal.

In Africa, early anthropoids diverged some 25 to 30 million years ago into lines leading to modern Old World monkeys and to apes. At first, apes were the most successful radiation, coming to occupy a range of rainforest and open woodland environments, while monkeys were quite rare. This condition changed radically some 10 million years ago when monkeys became abundant and apes rare. This change may have resulted from the advent of a more seasonably variable and drier climate. Ancestral Old World monkeys acquired specialized teeth suited to a leaf and fruit diet in drier climates. Also, the more rapid reproduction of monkeys may have made them more resistant to extinction than apes.

Some 6 to 8 million years ago, a line of apes diverged into two branches: one that gave rise to modern common chimpanzees and bonobos (pygmy chimpanzees) and a second branch that led to the group of bipedal apes that includes modern humans, the "hominins" (formerly known as "hominids," a term that now is used to refer to the great ape-human group) (Fig. 42.5).

Although the hominins today are represented by only one species, *Homo sapiens*, they were a remarkably successful and diverse group (de Sousa & Wood, 2007; Wood & Lonergan, 2008). The oldest known hominin radiation, australopiths, dates back at least 5 million years. These early hominins were bipedal, but skeletal traits suggest they retained considerable ability for climbing trees. Body size was rather small, and males were much bigger than females. Their brains were only slightly larger than those

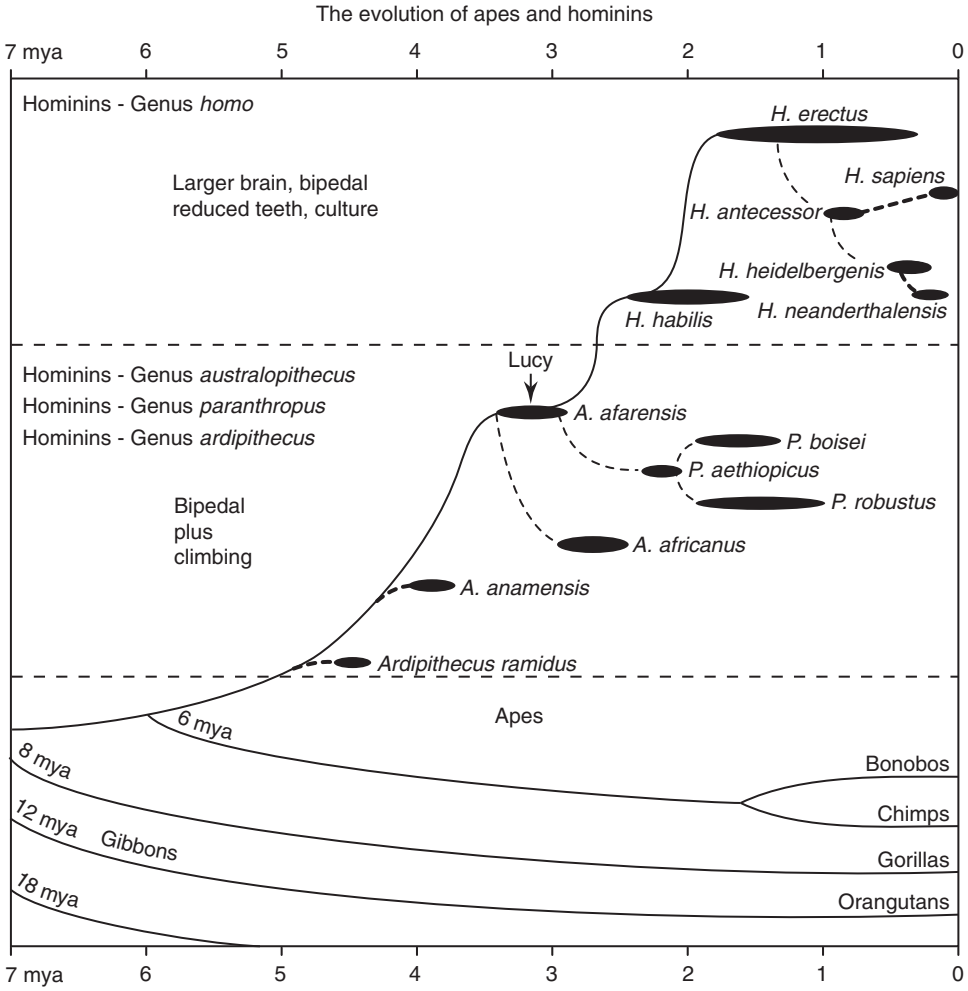

FIGURE 42.5 The evolution of apes and humans. Hominins include those extinct species that are judged to have been bipedal. *Ardipithecus ramidus* is generally thought to be bipedal while *Australopithecus* and *Paranthropus* clearly appear to have been bipedal. The age of the famous fossil, Lucy, is indicated. Relationships are somewhat uncertain, and more branches on the tree exist (Wood & Lonergan, 2008).

of apes of similar body size. Hominin traits may have emerged as adaptations to a drier environment with grassland and savanna. Early australopithecines soon gave rise to a number of species differing in body size and limb proportions, as well as in characteristics of the jaws and teeth and brain size. Our own genus emerged some 2 million years ago with *Homo habilis* (or "handy man," due to its use of stone tools). *Homo habilis* had a slightly increased cranial capacity compared to australopithecines, reduced face and teeth, and pelvic modifications for improved bipedal locomotion and the birth of neonates with larger heads. About 1.7 million years ago, *H. habilis* appears to have been replaced by *H. erectus*, a larger hominin with a further reduction in face and teeth and a larger brain. Shortly thereafter, *H. erectus* spread out of Africa to central Asia. *Homo sapiens* emerged from an African population of *H. erectus* some 250,000 to 300,000 years ago. Other members of the genus *Homo* coexisted with *H. sapiens* until recently. The Neanderthals, who adapted to a colder Europe and southwest Asia over 130,000 years ago, disappeared and were replaced by modern *H. sapiens* some 35,000 years ago. Neanderthals were shorter and more heavily built than modern humans, but had a comparable or slightly larger cranial capacity. As another known example, the fossilized bones of a probable descendant of *H. erectus*, *H. florensensis*, have been dated to 18,000 years old (Morwood et al., 2004). *Homo florensensis* were small (one meter tall and 20 Kg.) with brains (380 grams) smaller than those of the great apes. Over the last 15,000 years, some populations of modern humans have become smaller and have reduced their brain size, possibly as a result of a poorer diet as agriculture replaced hunting and gathering.

Chimpanzees and bonobos (also misleadingly known as "pygmy chimpanzees") appear to be our closest surviving relatives. Humans and chimpanzees are 98 to 99% similar in the coding sequences of genes, although the overall difference in DNA is closer to 96%, the difference reflecting the independent duplication, insertion, and deletion of DNA segments in the two lineages, and changes in noncoding regions that control gene expression. At present, we do not understand what changes in DNA account for the differences in brain size, anatomical organization, and function between humans and other apes, but this is an active area of research.

Presently, primates constitute a highly diversified taxonomic group (clade) that includes 14 families and over 350 species. Describing their brains is a challenging task, as the brains of only a few primate species have been extensively studied. It is clear, however, that primate brains vary enormously in size, and much of that variation reflects the 5000-fold range of body sizes found in primates—from the 40-gram mouse lemur to the 200-kilogram male gorilla (Fig. 42.6). Nevertheless, there are important differences in brain size that cannot be attributed to differences in body

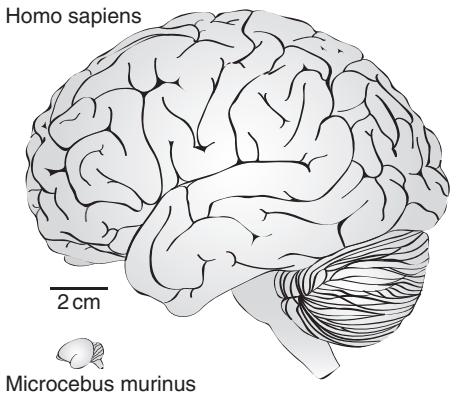

FIGURE 42.6 Lateral views of the brains of a human and a small prosimian primate, the mouse lemur, to illustrate the great range of sizes for present-day primates.

size. These variations in brain size reflect changes in the number of cortical areas and the size of individual areas. In addition, however, the internal architecture and intrinsic connectivity of areas were modified by evolution, as were the ways in which cortical areas are interconnected, reflecting the ways in which primates have diversified behaviorally. Despite these variations, primate brains also share a large number of features, some of which have been retained from nonprimate ancestors, and some of which emerged in early primates and have been widely retained.

Brains of Early Primates

Early primates resembled present-day lemurs and galagos in body form and brain shape, but the brains were significantly smaller in proportion to the body. Except for a lateral fissure and a calcarine fissure, features of the brains of most primates, there were only a few shallow fissures. We know most about the organization of neocortex and other parts of the brain of early primates from studies of present-day strepsirrhine primates, especially galagos, as they have been most extensively studied. The brains are smaller in proportion to body size than the brains of anthropoid primates, and they contain a number of distinctive features that are also found in the brains of other primates. While our focus is on cortical organization, we will also briefly describe subcortical features that were likely present in early primates, especially those for sensory systems.

Vision became a more important sense in early primates (Kaas, 2007b) as they came to rely less on olfaction and more on detecting prey and other food visually, and using eye-to-hand coordination to navigate in the fine branches of bushes and trees and bring food objects to the mouth. Compared to the nearest relatives of primates (tree shrews, flying lemurs, rabbits, and rodents), early primates had more forward-facing eyes, creating a larger binocular field of 130 degrees or more and a shift of the

BOX 42.2

WHY BRAIN SIZE IS IMPORTANT

Larger brains are generally thought to be computationally better because they usually have more neurons. However, growing bigger brains with more neurons creates a need for modifications in brain organization, and some solutions are likely to be common across taxa, allowing predictions about brain organization with brain size (Kaas, 2000). Enlarging a brain by having more neurons creates two related problems. If brain functions depend on each neuron maintaining the same proportion of connections with other neurons, then more neurons means more connections, which would be longer and take up more space. In addition, the conduction times of longer axons and dendrites would be longer, unless the thickness of the axons and dendrites were increased with the added length (Bekkers & Stevens, 1970). Thus, larger brains would have larger neurons with longer, thicker axons and dendrites. This suggests that brains would reach a maximum size, perhaps not much larger than that of present-day humans, because brain connections and glia would take up so much space with the addition of more neurons that such additions would be impractical. However, a design solution for such connection problems is for brains to become increasingly modular with larger size, so that short distance connections predominate, and only a few neurons have the long connections that are needed to coordinate the modular parts. Rodents do seem to increase the average neuron size with brain size, so that neuron densities greatly decrease as proportionately more space is devoted to glia and connections, but primates maintain neuron densities with increasing brain size, implying that average neuron size does not increase (Herculano-Houzel, Collins, Wong, & Kass, 2007). No other mammal, including elephants and whales with much larger brains, has the same number of neurons as the 1.5-kg human brain. A rodent with 86 billion neurons would need a 35-kg brain, well beyond the largest known brain mass of 9 kg for the blue whale (Herculano-Houzel, 2009). Whales and elephants may have evolved more modular brains as they acquired large brains, but they do not seem to have done it to the extent that seems to have occurred in the evolution of the large human brain. Over the course of the evolution of the large human brain, the neocortex of primates, which makes up the bulk of the human brain, acquired more cortical areas and more modular subdivisions of areas as brain sizes increased. As an example, the hemispheric specializations of the human brain presumably reduce the need for long connections between the two hemispheres.

A related issue is that large cortical areas are unlikely to function in the same manner as small cortical areas. Unless neurons compensate with larger dendrites and longer intrinsic connections as areas get larger, the computational window or scope of neurons will decrease (Fig. 42.10). For example, as a visual area gets bigger, individual neurons would evaluate information from less and less of the total visual field. This implies that as areas get bigger, their neurons become less capable of global center-surround comparisons and more devoted to local center-surround comparisons. Thus, some of the integrative functions of large areas must be displaced to smaller areas. The large V1 of the human brain preserves the detail of visual scenes, but perception depends on other, smaller visual areas. It is also apparent that changes in the sizes of dendritic arbors and the lengths of intrinsic axons in smaller areas would have more impact on the sizes of computational windows of neurons. Comparable changes in dendrites and axons would enlarge or reduce receptive field sizes more in a small than a large visual area. Because their functions are more modifiable by smaller structural modifications, smaller areas may be specialized more easily for different functions. Neurons in large areas typically do not have larger dendritic arbors and longer intrinsic connections, and indeed, they may have smaller dendritic arbors. Thus, V1 of primates has overall the smallest and most densely packed neurons of all cortical areas, and this is especially the case in large-brained anthropoid primates (Collins, Airey, Young, Leitch, & Kaas, 2010). In addition, although primary sensory areas are often larger in larger brains, they are not enlarged in proportion to the rest of cortex. Thus, in surface area primary visual cortex is less than three times larger in human brains than in the brains of macaque monkeys, whereas the neocortex as a whole is over 10 times larger. Neocortex in chimpanzee brains is one-fourth the size of the human neocortex, while primary visual cortex (V1) is about the same size. The general lack of proportional growth of cortical areas with brain size reduces the impact of the changing functions of areas with size, and reflects the addition of other smaller cortical areas.

retinal region of high receptor and ganglion cell density toward the center of the retina. These modifications permitted a fine-grain level of stereopsis in central vision and the detection of otherwise cryptic invertebrate prey. The retina had the three major classes of ganglion cells that are found in all extant primates; the small koniocellular (K), medium parvocellular (P), and large magnocellular (M) ganglion cell classes, which are named after their layers of termination in the lateral geniculate nucleus of the visual thalamus. Detailed vision depends on the

P cells, which constitute the majority of retinal ganglion cells in all primates. K cells constitute only about ten percent of the ganglion cells in diurnal primates, but they are more common in nocturnal primates, and would have been so in early primates since they were nocturnal. M cells respond to visual change such as that commonly produced by object movement. M cells represent roughly ten percent of the ganglion cells. The ganglion cells project to a number of small brainstem targets, as well as to the dorsal lateral geniculate nucleus (LGN) and the superior colliculus (SC).

Early primates and all subsequent primates differed from their nonprimate ancestors by representing only the contralateral visual hemifield via the nasal retina of the contralateral eye and the temporal retina of the ipsilateral eye in the superior colliculus. Nonprimate mammals preserve the ancestral mammalian condition, in which the complete retina of the contralateral eye projects to SC. This modification in primates likely promoted the coordination of eye movements and binocular vision.

The other major target of the retina, the LGN, also became specialized with the first primates. A common pattern of four main layers emerged with two ventral magnocellular layers and two dorsal parvocellular layers, with the outer layers for the contralateral eye and the inner layers for the ipsilateral eye. As early primates were nocturnal, they also likely had two thin koniocellular layers between the P layers, one for each eye, as in all extant strepsirrhines. These layers did not persist in anthropoid primates, in which the K cells remained but were scattered between the other layers. In many anthropoid primates, including humans, the P-cell layers became massive, and subdivided into four or more sublayers that allowed further emphasis on detailed object vision. The visual pulvinar was also organized in a distinctive primate specific pattern, with an inferior pulvinar of at least three divisions and a lateral pulvinar of possibly two divisions.

In early primates, the fossil record indicates that visual cortex occupied a large portion of neocortex as occipital cortex extended caudally to cover the midbrain and much of the cerebellum, and temporal cortex extended forward and down as in present-day galagos (Fig. 42.7). This visual cortex was divided into a number of visual areas, some of which appear to be unique to primates. Other visual areas retained from nonprimate ancestors became modified to subserve the increased role for vision in early primates.

The arrangement of some of the visual areas that were likely present in the visual cortex of early primates are shown on a surface view of the neocortex of one hemisphere of a galago brain, after the neocortex has been separated from the rest of the brain and flattened so that hidden surfaces are visible (Fig. 42.7). As in extant primates, early primates had three early stages of cortical processing: V1, V2, and V3. V1 was large and densely packed with small layer 4 cells, more so than any other cortical area (Collins et al., 2010), as a way to promote detailed vision. In primates, but not in the close relatives of primates, V1 has a distribution of cytochrome oxidase "blobs" that may represent a specialized output of the K-geniculate layers (Casagrande & Kaas, 1994). All primates also have an orderly arrangement of direction-of-motion and stimulus-orientation neurons in V1 that look like pinwheels from the surface. This feature of V1 likely predated the evolution of primates, as the close relative of primates, tree shrews, also have orientation-specific pinwheels in V1, but V1 of more distantly related rodents and lagomorphs does not. The segregation of eye of origin information into ocular dominance bands or patches is also a specialization in V1 of primates, being absent in tree shrews, rodents, and rabbits. Ocular dominance columns evolved independently in carnivores, as did blobs.

V2 is another area that is common to most mammals, while being specialized in primates by having three repeating classes of band-like modules that cross the width of V2, the so-called thin, pale, and thick stripes, each receiving a different type of input from V1 and projecting differently to higher order visual areas. These modules exist in strepsirrhine as well as in anthropoid primates, but they are much more histologically distinct in anthropoids. These band-like modules are not found in the relatives of primates, suggesting that they evolved in early primates and were further differentiated in anthropoids.

V3 also exists in all studied primates, although its existence as a field bordering V2, with representations of both the upper and lower visual quadrants, has been questioned. There is no compelling evidence yet for a V3 in the close relatives of primates, despite the clear evidence for a V3 type of area in carnivores, so V3 may be a primate specialization. However, V3 has only recently been well characterized in primates, and the close relatives of primates should be further investigated.

The middle temporal visual area, MT, is a visual area that is recognized widely as being present in all primates. MT receives most of its activation inputs from the M ganglion cell population via direct and indirect projections from V1, and is highly involved in analyzing visual motion. MT is part of a constellation of functionally related areas, MST, FST and MTc (V4t), that all appear to be unique to primates, although homologues of MT in other mammals have been suggested. The dorsolateral visual area (DL or V4) is another area that may be a primate specialization, as is the dorsomedial visual area (DM or V3A). A number of other visual areas have been proposed, especially for macaque monkeys and humans. But for the most part, these areas have not been well defined across a range of primate species. Nevertheless, primates share as many as 10 to 15 visual areas. All primates appear to have their visual systems organized into dorsal and ventral streams of visual processing for guiding actions and object vision, respectively. Dorsal-stream

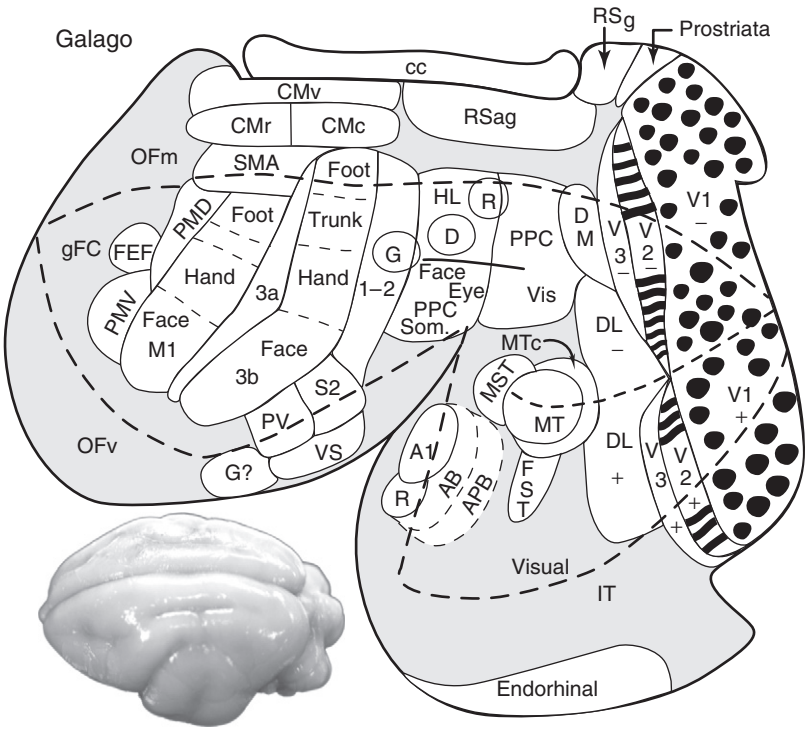

FIGURE 42.7 A surface view of the flattened neocortex of a prosimian primate, *Galago garnetti*, showing some of the proposed visual, somatosensory, auditory, and motor areas. Visual areas include the primary (V1) and secondary (V2) areas, common to most mammals, but with the modular subdivisions (blobs in V1; bands in V2) characteristic of primates. As in other primates, galagos have a third visual area (V3), a dorsomedial area (DM), a middle temporal area (MT), a dorsolateral area (DL), a fundal-sucal-temporal area (FST), a middle superior temporal area (MST), and an inferior temporal visual region (IT) with subdivisions. Posterior parietal cortex (PP) contains a caudal division with visual inputs and a rostral division with sensorimotor functions. The auditory cortex includes a primary field (A1), a rostral area (R), and an auditory belt (AB), which includes several areas, and parabelt auditory cortex (APB). The somatosensory cortex includes a primary area (S1 or 3b), a parietal ventral area (PV), a secondary area (S2), a parietal ventral area (PV), a somatosensory rostral belt (RS or 3a), and a somatosensory caudal belt (CS or possibly area 1 or areas 1 plus 2). A gustatory area (G?) may have been present. Motor areas include a primary area (M1), ventral (PMV) and dorsal (PMD) premotor areas, a supplementary motor area (SMA), a frontal eye field (FEF), and other motor areas on the medial wall of the cerebral hemisphere. The thick dashed line encloses cortex that can be seen on a dorsolateral view of the intact brain (lower left). Granular frontal cortex (gFC); orbital frontal medial cortex (OFm); orbital frontal ventral cortex (OFv); ventral, rostral, and caudal cingulate motor areas (CM); retrosplenial granular and agranular areas (RSg and RSug); corpus callosum (CC). *Modified from Kaas (2007b).*

motion-sensitive visual areas such as MT project to posterior parietal cortex and object related visual areas such as DL/V4 project to visual areas of the inferior temporal lobe. Both parietal and temporal areas relay to frontal cortex (Preuss & Goldman-Rakic, 1991).

The auditory system has been less extensively studied than the visual system in primates, and subcortical processing stations such as the inferior colliculus and medial geniculate complex are assumed to be organized in a manner similar to those of other mammals. However, mammals vary considerably in the arrangement of auditory cortical areas (Kaas, 2011b). Primates are generally thought to have three early stages of auditory processing, a primary core, a surrounding belt, and an adjoining parabelt (Kaas & Hackett, 2000). The primary core in all primates appears to include at least two areas: A1 and a rostral area, R. Both represent tone frequencies from high-to-low, and have the histological, connectional, and functional properties of primary sensory cortex. Little is known about how belt and parabelt regions are organized across primate taxa, or in any strepsirrhine primates, so little can be inferred about early primates. However, given the presence of at least two primary areas in rodents, as well as adjoining secondary areas, early primates likely retained two or more primary areas and some secondary areas from earlier nonprimate ancestors.

The somatosensory system of early primates was likely similar to those of other mammals at early stages of processing. The system for object recognition included the dorsal-column-medial lemniscus pathways to the ventroposterior nucleus of the somatosensory thalamus. This pathway was more devoted to the tactile receptors of the glabrous skin of the forepaw (hand) than in most mammals, and this skin had larger representations at thalamic and cortical levels. Nevertheless, the thalamic and cortical representations of the face, teeth, and tongue were quite large, with representations of both ipsilateral and contralateral teeth and tongue. The area generally recognized

as area 3b (S1 proper) in anthropoid primates constitutes the homolog of nonprimate S1, although it is common in descriptions of somatosensory cortex in humans to include areas 3a, 3b, 1, and 2 in "S1." In strepsirrhines and some New World monkeys, only one representation of the contralateral body has been found caudal to area 3b, so it is not clear if this region is homologous to area 1 or to both areas 1 and 2. Here we propose that early primates had a single area, corresponding to areas 1 plus 2 of anthropoid primates. Area 3a is a proprioceptive area with inputs from the ventroposterior superior (VPS) nucleus of the somatosensory thalamus. Area 3a, or dysgranular somatosensory cortex was likely retained from early mammals, as were areas S2, PV, and gustatory cortex (G). The ventral somatosensory area (VS), with two divisions, appears to exist in most primates, but has not been identified in other mammals.

Primary motor cortex (M1) and likely one or more premotor areas are found in all primates and were retained from nonprimate ancestors, as M1 and a premotor area are found in rodents and tree shrews (Remple, Reed, Stepniewska, Lyon, & Kaas, 2007). All primates also have dorsal and ventral premotor areas (PMD and PMV), a supplementary motor area (SMA), and two or more cingulate motor areas. The arrangement of these motor fields is remarkably consistent across primate taxa, although premotor areas clearly have functionally distinct subdivisions in some anthropoid primates. Frontal cortex has retained divisions of orbital frontal cortex, while the granular prefrontal cortex is unique to primates (Preuss, 1995). Granular prefrontal cortex is small in strepsirrhines but includes several areas common to primates, including the frontal eye field (FEF). The prefrontal cortex underwent substantial enlargement and elaboration in anthropoid evolution, and areas like the principalis cortex (area 46) of macaques, which mediate higher cortical functions, are most likely anthropoid or catarrhine specializations.

Another region that appears to have changed markedly with the origin of primates is posterior parietal cortex (PPC). In rodents and tree shrews there is little cortex that could be defined as posterior parietal cortex, and visual and somatosensory information reaches motor cortex more directly. However, all primates have a large region of posterior parietal cortex, and part of this cortex has an orderly arrangement of functionally distinct zones that are involved in reaching, defensive, grasping (zones G, D, and R in Fig. 42.7) and other movement sequences (Kaas, Gharbawie, & Stepniewska, 2011). In strepsirrhine galagos, the caudal half of PPC receives most of the visual input, while projecting to the movement-related zones in the rostral half of PPC. Rostral PPC has dense somatosensory inputs, and projects to functionally matched zones in motor and premotor cortex. The organization of PPC is more complex in anthropoid primates, especially in humans where PPC is significantly involved during tool use. PPC also has strong connections with granular prefrontal cortex, and with the higher-order multisensory cortex of the temporal lobe. In primates, these three cortical regions are connected to a common thalamic nucleus, the dorsal pulvinar (also known as the medial pulvinar), and like these cortical regions, the dorsal pulvinar has no obvious homolog in nonprimate mammals (Preuss, 2007).

Brains of Early Anthropoids

The anatomy of early anthropoids suggests that an emphasis on high-acuity, diurnal vision and a reduced emphasis on smell were important in their evolution. The endocasts of the skulls of early anthropoids indicate that the visual cortex of the temporal lobe was more expansive than in strepsirrhines, and overall the brains were considerably larger relative to body size. After the divergence of New World and Old World anthropoids, brain size increased independently in both groups. New World monkeys cover a particularly large range of body and brain size. Since the degree of folding depends on the absolute size of the brain, the smaller-brained New World monkeys like marmosets, owl monkeys, and squirrel monkeys have relatively smooth brains, while the larger species, such as capuchins, spider monkeys, and howler monkeys, have well-fissured brains that resemble (at least superficially) the convoluted brains of Old World monkeys

Both Old World and New World monkeys have all of the areas of the neocortex described for strepsirrhines, as well as some additional areas. Most notably, the somatosensory cortex has been altered so that areas 3a, 3b, 1, and 2 are well differentiated from each other, with each area corresponding to a separate representation of receptors of the contralateral body surface (Kaas, 2007b). Within S1 (area 3b), the proportional representation of body parts varies somewhat across species, so that in some monkeys as much as half of the area is devoted to the face and oral cavity. The hand is also prominently represented, especially in monkeys such as macaques. Some New World monkeys, such as spider monkeys, have a large representation of the hairless (glabrous) ventral skin of their highly tactile, prehensile tail. Marmosets appear to lack a separate area 2, a field that is responsive to tactile stimuli and muscle movements in other monkeys. This may be a consequence of brain size reduction in marmosets, which have evolved smaller brains and bodies from larger ancestors, and transformed their nails back into claws. In all anthropoids, S2 and PV appear to have lost activating inputs from the ventroposterior nucleus of the somatosensory thalamus, and they depend on inputs from areas 3a, 3b, 1, and 2 (Fig. 42.8). S2 and PV receive modulatory inputs from the ventroposterior inferior nucleus. Thus, processing in the somatosensory system became more serial than parallel with the advent of monkeys. Other

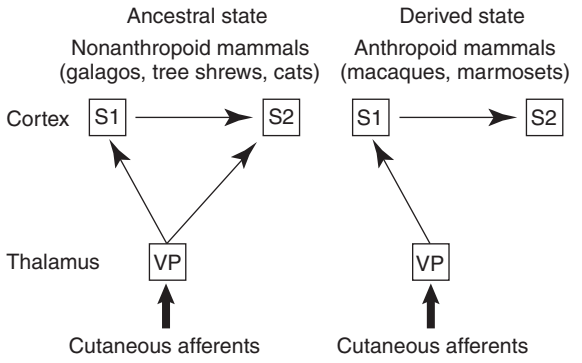

FIGURE 42.8 Somatosensory processing in prosimian primates and anthropoid primates. The processing in anthropoids is serial, rather than parallel and serial. Because the prosimian type is also found in a number of nonprimate mammals, we infer that this is the ancestral state and the anthropoid type is the derived or newly evolved state. The ventroposterior nucleus (VP) of the somatosensory thalamus and the first (S1) and second (S2) somatosensory areas of the cortex are shown.

differences likely exist between anthropoids and strepsirrhines in the somatosensory portions of the lateral sulcus, and more research is needed.

Currently, there is much interest in how the visual cortex of monkeys is subdivided into areas and how these visual areas function in behavior (Orban, Van Essen, & Vanduffel, 2004). Elaborate proposals have been presented, but considerable uncertainty remains. In Old World monkeys, over 30 visual areas have been proposed, and it seems likely that anthropoids in general have more visual areas than strepsirrhines, although the full extent of this difference is not yet clear. The auditory cortex of strepsirrhines has been poorly studied, and it is unclear whether they share the same core-belt-parabelt organization that has been identified in anthropoids. The proposed subdivisions of the motor cortex in strepsirrhines and anthropoids are quite similar, although some of the premotor areas of strepsirrhines have been subdivided into two or three areas in Old World monkeys. Finally, as noted above, the higher-order temporal, parietal, and prefrontal cortex was greatly expanded in anthropoid evolution, and comparative studies of (strepsirrhine) galagos and (anthropoid) macaques indicate that macaques possess a number of areas in prefrontal cortex that galagos lack. The same is likely true of the parietal and temporal cortex, but these regions have not been compared as comprehensively as prefrontal cortex.

Evolution of Hominin Brains

Understanding human brain evolution requires determining what changes took place in the human brain in the 6 to 8 million years since the human and chimpanzee-bonobo lineages diverged. For a long time, nearly all one could say about these changes is that human brains got larger (Box 42.2), reaching about three times the volume of those of chimpanzees and other great apes, although humans are only slightly larger than chimpanzees in adult body size (Fig. 42.9). From the fossil record, we also know that most of this increase took place in the last ~2 my, with the emergence of genus *Homo*, and that there were several species of this genus with brains as large as our own, although only *Homo* sapiens remains today. But the fossil record cannot tell us much about what went on inside the brain, which is what we really want to know if we are to understand the evolution of human-specific behavioral and cognitive abilities, such as language and the ability to represent and reason about abstract or invisible causes, such as mental states (Povinelli & Preuss, 1995; Premack, 2007).

To understand changes in internal organization, we need to compare human and ape brains directly and identify the ways in which they differ. This has posed a great challenge, because neither humans nor apes can be studied with the invasive and terminal techniques so widely used with model animals in the neurosciences. With the development of noninvasive neuroimaging techniques, however, along with the proliferation of antibodies and other molecular tools for probing brain structure in postmortem material, and the rise of comparative genomics, the comparative approach to studying human brain evolution has entered a new and productive era.

Traditionally, it was postulated that the higher-order regions of the frontal, parietal, and temporal lobes (the classical "association" cortex) underwent great expansion in human evolution. This view was recently called into question by comparative structural neuroimaging studies that found that the relative proportions of the frontal, parietal, and temporal lobes are similar in great apes and humans, notwithstanding the much larger absolute size of the human brain. The fact remains, however, that the primary sensory cortical and thalamic structures are of roughly the same absolute size in humans and great apes, while other regions of cortex in humans are much larger in absolute terms. This is consistent with classical accounts of human brain evolution that emphasize the expansion of higher-order regions (Preuss, 2011).

One of the signature specializations of *H. sapiens* is of course language, and it has often been assumed that the evolution of language involved the evolution of specialized language areas in the brain, such as Wernicke's area in the temporoparietal cortex and Broca's area in the frontal lobe. Current evidence, however, strongly suggests that homologues of Wernicke's and Broca's areas are present in apes and monkeys, which in turn suggests that evolution "recruited" these areas and modified them to support language functions. A recent comparative neuroimaging study with diffusion tensor imaging (DTI) has demonstrated that the major pathway between the frontal and temporal language territories (the arcuate fasciculus)

has different connectivity patterns in humans and chimpanzees, with humans showing much stronger connections with the middle temporal gyrus, which in humans is involved in representation of word meanings (Rilling et al., 2008). This is one of several pieces of evidence indicating that the middle temporal cortex expanded greatly in human evolution, displacing the temporal lobe visual areas posteriorly and inferiorly in humans, compared to their location in monkeys.

Since most humans are left-hemisphere dominant for language, it is natural to assume that human brains are more strongly lateralized than those of apes. Surprisingly, apes share some of the gross asymmetries of brain morphology found in humans, including a larger *planum temporale* (the region of superior temporal cortex often identified with Wernicke's area) on the left than the right. Microscopic studies of postmortem tissue, however, indicate that Broca's area, which is larger on the left in humans, is not asymmetrical in size in chimpanzees.

Humans are unusual among mammals in their facility in making and using tools. Functional imaging studies in humans reveal that these activities tap specific, higher-order regions of parietal and frontal cortex (Stout, Passingham, Frith, Apel, & Chaminade, 2011). Direct comparison of brain activity in humans and macaques during tool use indicates that humans have a small territory of left inferior parietal cortex that is selectively responsive when humans view tools that are used to grasp objects, whereas macaque neural activity does not differ between viewing grasping actions of hands and tools (Peeters et al., 2009). It is unclear whether the tool-specific area of humans is a novel area or a modified form of an area present in other primates. A similar issue is raised by the observation (Vanduffel et al., 2002) that the cortex of the intraparietal sulcus is much more responsive to certain types of object movement in humans than in macaques: are these new areas or modified areas? We cannot answer these questions without more detailed comparative studies, with studies of chimpanzees being especially important. In any case, however, it is likely that human cortex is tuned to dimensions or aspects of movement in ways that distinguish humans from at least most other anthropoid primates.

Microscopic studies have also identified specializations of cellular and molecular biology of humans. For example, humans and great apes possess a distinctive type of large, bipolar cell (spindle cells or Von Economo neurons) in anterior cingulate and insular cortex. While present in apes as well as humans, they are especially large and numerous in humans. Similar cells are not found in other anthropoid primates. Interestingly, a similar cell type has evolved independently in whales and elephants, suggesting that this morphology is part of an adaptation for rapid neural communication in large-brained animals (Allman et al., 2011; Watson & Allman, 2007).

The previous example illustrates that evolution can modify areas that are phylogenetically ancient, and not only areas that are evolutionarily new or functionally higher-order. Another example comes from primary visual cortex. Several lines of evidence suggest that apes and humans reduced or lost a projection from the lateral geniculate nucleus to cortical layer 4A, the upper part of cortical layer 4. (Comparative studies indicate that the upper parts of layer 4 of anthropoids, 4A and 4B, are actually parts of layer 3; see Casagrande and Kaas (1994). In addition, humans further modified layer 4A, adding a

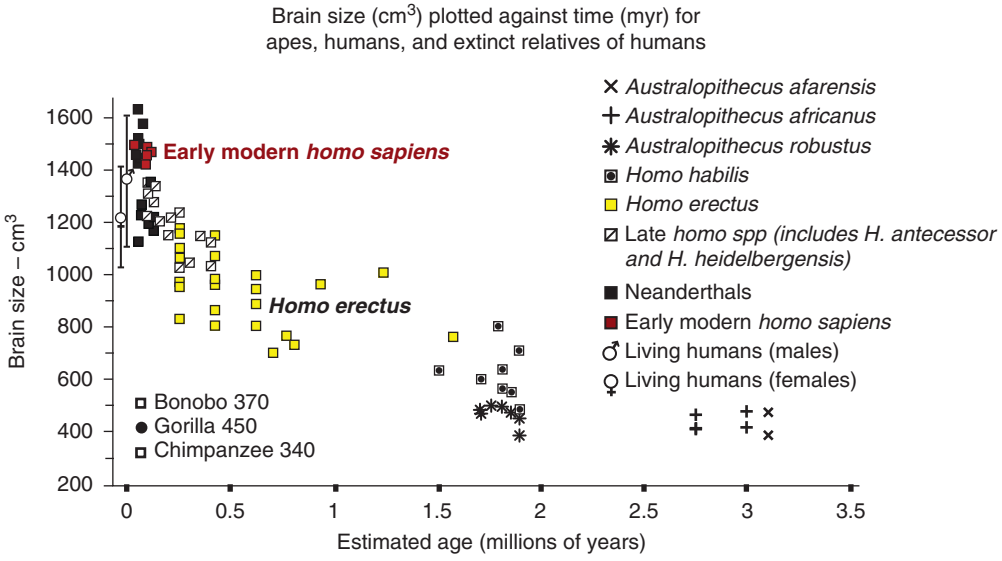

FIGURE 42.9 Evidence for the rapid growth of brains of hominins over the last two million years. The brain sizes of modern chimpanzees and gorillas have been added for comparison. *Modified from McHenry (1994).*

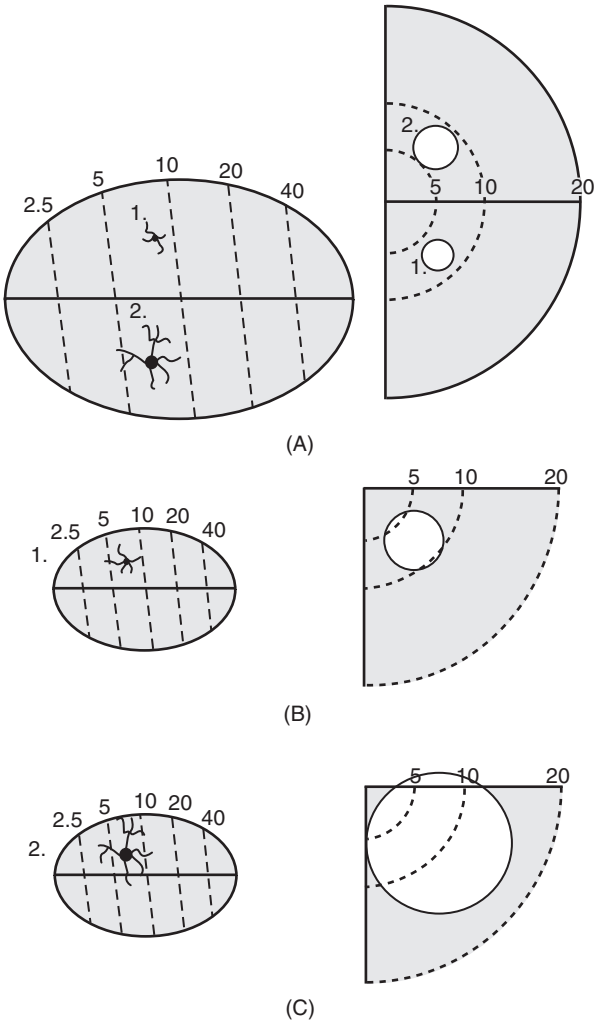

FIGURE 42.10 The effects of varying the horizontal spread of dendritic arbors of neurons in large (A) and small (B and C) visual areas. An increase in arbor size (1 to 2) in a large area (A) produces little change in receptive field size (circles 1 to 2 in the central 20° of the visual hemifield on the right), whereas such a change (B to C) in a small area changes the scope of the receptive field greatly. Thus, the functions of small areas are changed more dramatically by small morphological adjustments. Surface view schematics of retinotopically organized visual areas are on the left, whereas schematics of receptive fields in the visual hemifield and the lower visual quadrant are on the right. *From Kaas (2000).*

novel set of compartments that stain for molecules usually associated with the magnocellular processing stream, the part of the visual system involved in motion analysis (Preuss & Coleman, 2002; Preuss, Qi, & Kaas, 1999). These modifications could influence the functional properties of higher-order areas, including the intraparietal cortex, since V1 is the major source of visual information for the rest of the cortex.

Another new area of active research that provides information about human brain evolution comes from comparative genomics, the goal being to identify evolutionary changes in gene sequences and gene expression relevant to human brain evolution. Although it is commonly assumed that humans and chimpanzees are nearly identical genetically, the most recent genomic comparisons have revealed a plethora of differences, including hundreds of adaptive changes in protein coding sequences; myriad deletions, duplications, and insertions of blocks of DNA; changes in transcription factor binding sites; and differences in the amounts of specific genes and proteins expressed in the brain (Varki & Nelson, 2007). At present, we do not understand what changes in DNA account for the differences in brain size, anatomical organization, and function between humans and other apes, but this is an active area of research. There is, however, intriguing evidence suggesting that the expression of genes involved in synaptic plasticity was modified in human evolution, and that human brains are adapted to sustain unusually high rates of energy metabolism (Cáceres et al., 2003; Fu et al., 2011; Preuss, 2011).

CONCLUSIONS

Based on comparative studies and the fossil record, we conclude that early mammals had small brains with little neocortex and few functional subdivisions (areas or fields) of cortex. Vision was emphasized in the early primates, and the visual cortex in the temporal and occipital lobes was enlarged. These primates also had several unique features of the visual system, including new visual areas such as MT, distinctive kinds of modules in V1 (blobs) and V2 (bands), separate magnocellular and parvocellular layers in the lateral geniculate nucleus, and a representation in the superior colliculus restricted to the contralateral visual hemifield. Several premotor areas were present, whereas the somatosensory system was relatively primitive. Later anthropoid primates had larger brains, more neocortex, and more areas of neocortex. The somatosensory cortex had expanded and included the four strip-like areas on the anterior parietal lobe, areas 3a, 3b, 1, and 2. We know little about possible specializations of the brains of apes. However, over the last 6 million years of evolution in the human lineage, brains increased three to four times in size, due mainly to the enlargement of the cortex. Although the relative proportions of the different cortical lobes remain similar in humans and apes, the available evidence suggests that the cortex did not expand uniformly in human evolution, as the higher-order regions of frontal, temporal, and parietal lobes are much larger in absolute terms in humans than in apes, while human primary sensory areas are about the same absolute size as those of apes. The expansion of nonprimary cortex was probably accompanied by a further increase in the number of cortical areas, modifications leading to functional and anatomical asymmetries in the two cerebral hemispheres, specializations for language and cognition, and larger expanses of prefrontal, parietal,

and temporal cortex. The cortex of the larger brains had many more neurons with a greater proportion of tissue devoted to subcortical white matter connections relative to cell bodies (Herculano-Houzel, Mota, Wong, & Kaas, 2010), and presumably had a higher ratio of local connections to long-distance connections.

Further progress in understanding the evolution of the human brain can be achieved with current methods of investigation. We have the opportunity to learn much about the similarities and differences among the brains of various primates. Neuroscientists have generally concentrated on studies of brain features that are widely shared, but we need to know more about the differences in brain structure and function that make us distinctively human.

CHAPTER

43

Cognitive Development and Aging

The human brain has evolved over a very extensive period (see Chapter 42), but an individual human brain develops rapidly over the first few years of life, allowing the nearly helpless human infant to gain control of locomotion, language, and thought. The story of brain development in the early years of infancy through adolescence occupies the first part of this chapter. This is followed by consideration of the cognitive changes that occur during this period of the life span and how these capacities are altered over the course of normal aging. The final parts of the chapter discuss pathological processes that affect cognitive development in childhood and adolescence and can cause devastating cognitive impairment in the elderly.

BRAIN DEVELOPMENT

Basic Concepts of Brain Development

Brain Maturation Progresses Well into Adolescence

Brain development is an organized, predetermined, and highly dynamic multistep process that continues beyond birth into the postnatal period, well into adolescence in humans. Most of our knowledge about human brain development has been obtained through analyses of postmortem specimens and, more recently, powerful neuroimaging techniques. These approaches have not only provided extensive information on how the size and shape of different brain regions change from conception through adulthood in relation to normal cognitive development (Fig. 43.1) but they also have opened unparalleled opportunities for identifying abnormal patterns of development in various psychiatric disorders. The brain grows rapidly in the first 2 years of life, by which time it has achieved 80% of its adult weight. Thereafter, brain growth is slower, reaching over 90% of average adult weight by the sixth year. The development of the cerebral cortical surface proceeds gradually from the flat (lissencephalic) brain of the fetus to the adult gyral pattern at birth. Cortical development in most mammals is broadly divided into two phases. The first is a genetically determined sequence of events occurring *in utero* that can be modified by both the local environment within the fetal nervous system and the maternal environment. The second phase is one that occurs in the perinatal period when the connectivity of the cortex becomes sensitive to patterns of neural activity. Glial processes also critically participate in normal development, supporting cell proliferation, differentiation and guidance, and the formation of myelin sheets around axons. Brain structure size, and developmental trajectories are highly variable and sexually dimorphic.

The Cortex Thickens during Development

Development of the cortical mantle in the human brain was documented extensively in the classic studies of Conel (1939–1963). Longitudinal neuroimaging studies in large samples of children have shown changes in volume of cortical gray matter that are nonlinear and regionally specific (Lenroot & Giedd, 2006). Volume of gray matter increases during preadolescence, with a maximum occurring around 10–12 years of age in the parietal lobe, 11–12 years of age in the frontal lobe, and 16–17 years of age in the temporal lobe, followed by a decline in postadolescence. Although neuroimaging techniques lack the resolution to identify the specific structural modifications that underlie changes in cortical volume during development (i.e., cell number, synapse density, myelination), they do indicate that development of the human cerebral cortex is highly dynamic over time and varies across different cortical areas. Developmental trajectories during

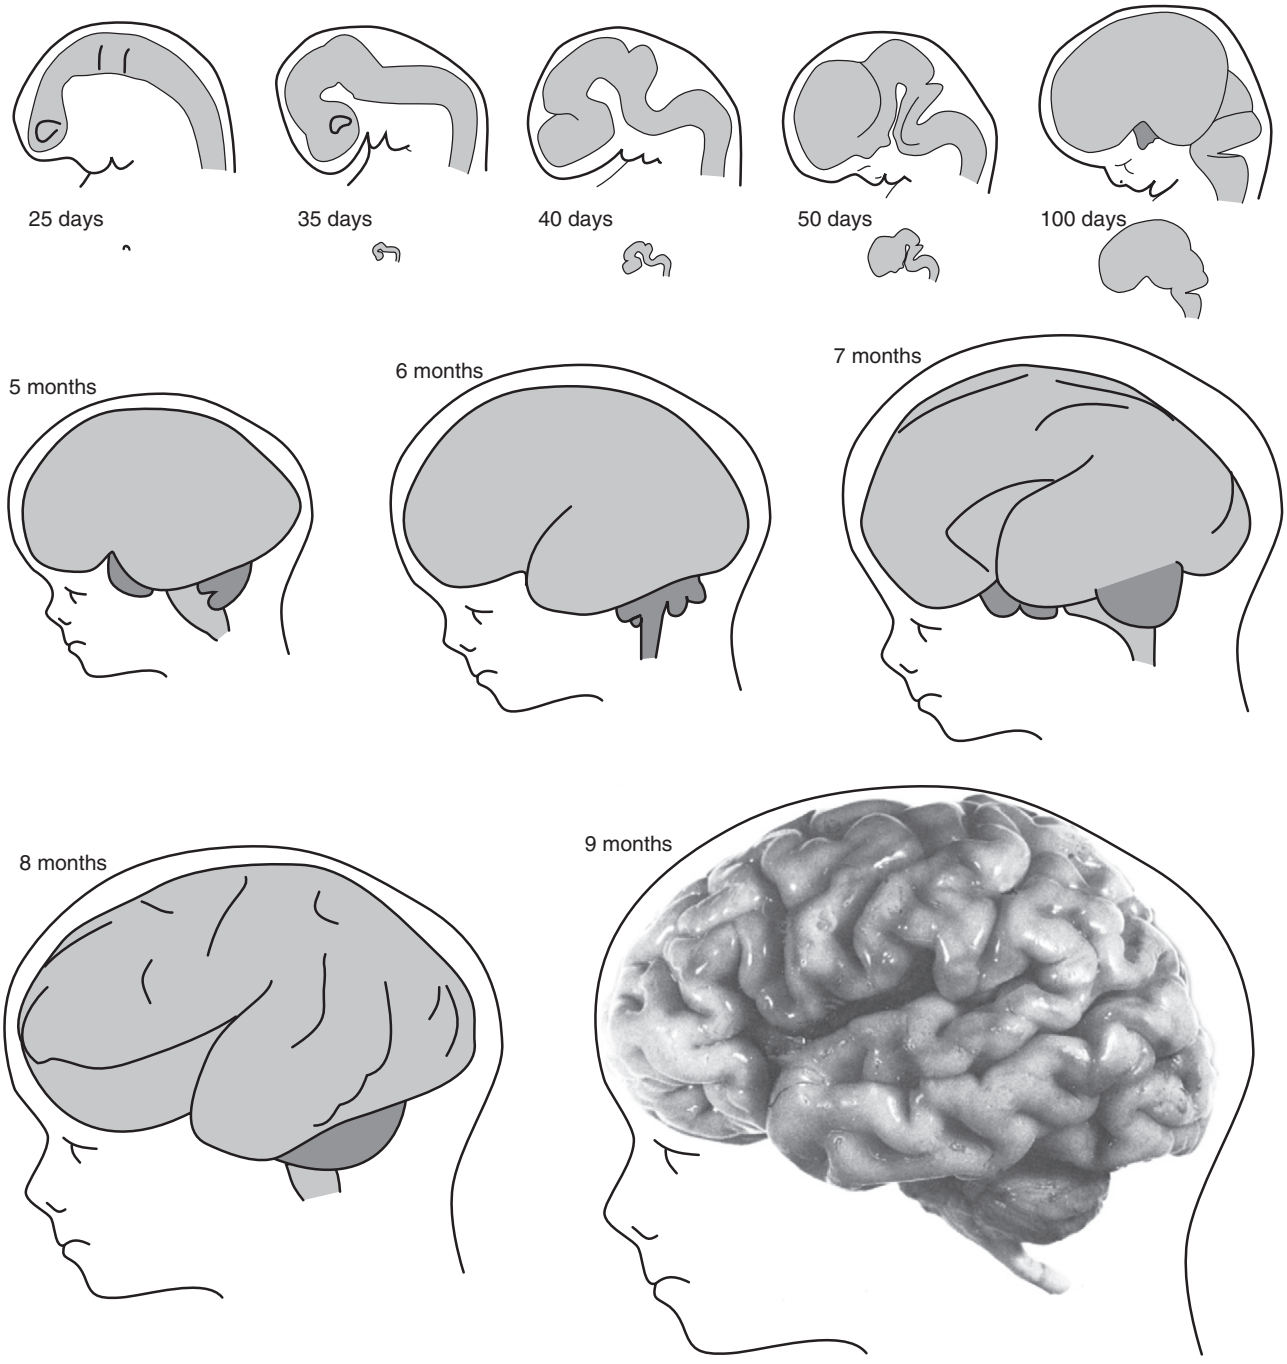

FIGURE 43.1 The size and form of the human brain as it develops through gestation and early infancy.

childhood and adolescence also differ between male and female brains (Lenroot et al., 2007), suggesting that sex steroids play a significant role (Raznahan, Lee et al., 2010).

Dendritic Spine Number Increases During Development

The formation of dendritic spines and the time course of changes in the length and branching patterns of dendrites have been described for visual and frontal cortical areas in humans. Within the visual cortex, peak spine density is achieved around 5 months of age; this number then decreases until adult values are obtained around 21 months of age. Progressive elongation of dendrites occurs up to 24 months. Dendritic development in the visual system reaches mature levels in deep cortical layers earlier than in superficial layers, displaying the "inside-out" pattern of development that is characteristic of neurogenesis and migration (Chapter 15).

Development and maturation of the frontal cortex proceed more slowly. Whereas neuronal density in the primary visual cortex (V1) reaches adult levels by 4–5 months, neuronal density in the frontal cortex fails to reach adult levels even at 7 years of age. Additionally, by 2 years of age, dendritic length in frontal cortex (which is mature by 18–24 months in V1) is only half that found in adults. Left–right asymmetries exist in the dendritic branching patterns of pyramidal neurons within layer V of the inferior frontal and anterior precentral cortex. During the first year, growth is more advanced on the right side, but by 6–8 years of age, the maturation of distal dendrites on the left exceeds that of the right.

Synapses First Increase and Then Decrease in Number

As in the brains of other animals (Chapter 18), the immature human brain contains many more synapses than the mature brain (Huttenlocher, 1990). Within the primary visual cortex, synaptic density increases gradually during late gestation and early postnatal life, and then doubles from 2 to 4 months of age. After age 1, however, there is a decline in synaptic density until adult values (50 to 60% of the maximum) are attained at about 11 years. The time course of the decrease in synaptic density varies across different cortical layers (Fig. 43.2). The decrease does not display the "inside-out" pattern of development; rather, there is a considerable decrease, over time, in the number of synapses in every layer. A postnatal increase and subsequent decline in synaptic density also occurs in the middle frontal gyrus (layer III), but these frontal cortex changes take place over a longer time course than in the primary visual cortex (Fig. 43.3). The maximum density of synapses occurs around 1 year of age (compared to 4 months in the visual cortex), and adult values are not reached until roughly 16 years of age (compared to 7–11 years for the visual cortex).

In summary, these quantitative anatomical results suggest that, in contrast to other animals (Chapter 18), programmed cell death plays only a limited role in human brain development. Synapse elimination in humans and other primates exceeds that observed in many species, however, suggesting that modifications in synaptic connectivity may be particularly important for the development of complex nervous systems. Current findings are consistent with a role for incoming afferent input in selectively stabilizing functional synapses and in eliminating or suppressing inactive contacts. The exuberant connectivity observed during development may also support compensatory processes in cases of early brain trauma, allowing surviving synapses to assume functions normally subserved by damaged inputs.

Postnatal Refinement of Synaptic Contacts Occurs in the Neostriatum and Hippocampus as Well

Although the morphological development of certain subcortical structures, such as the thalamus and cerebellum, is nearly complete at birth, other structures continue to mature into early postnatal life. In the neostriatum, synaptic density increases until the end of the first postnatal month, and changes in neuronal and neuropil morphology are observed until 2–4 months postnatally. Refinement of synaptic contacts proceeds until the end of the first postnatal year when the striatal neurochemical mosaic attains adult characteristics. In the hippocampus, neurons have reached their destination at birth in all CA

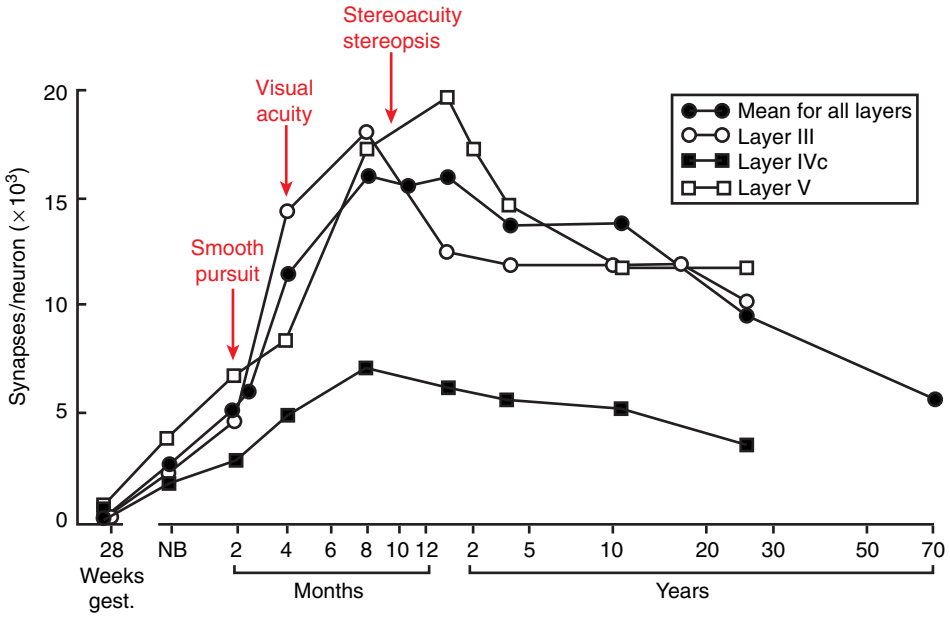

FIGURE 43.2 Variations in the density of synapses of different cortical layers of the human primary visual cortex during development. Arrows point to the approximate periods of emergence of various prefrontal cortex functions. NB, newborn. *Adapted with permission from Huttenlocker (1990) and Chugani, Phelps, and Mazziotta (1993).*

fields, but immature cells continue to accrue within the dentate gyrus throughout the first year of life. In addition, continued dendritic remodeling in the hippocampus has been observed as late as the 5th postnatal year in humans (Seress, 2008). Myelination in the subicular and presubicular regions, a key relay zone between the hippocampus and many cortical areas, continues through adolescence and adulthood (Benes, Turtle, Khan, & Farol, 1994) with female subjects showing a greater extent of myelination between the ages of 6 and 29 than males. These changes are accompanied by corresponding changes in the volume of the hippocampus during early development (Giedd et al., 1996).

White Matter Increases Throughout Childhood and Adolescence

In contrast to the inverted U shape of gray matter development, white matter maturation in the brain continues long after the gray matter has reached its definitive volume (Lenroot & Giedd, 2006; Klingberg, 2008). In general, myelination progresses from caudal to cephalic. Thus, the brainstem myelinates prior to the cerebellum and basal ganglia. Similarly, the cerebellum and basal ganglia myelinate prior to the cerebral hemispheres. Sensory and motor systems display mature myelination within the first 2 years of life. However, nonspecific thalamic radiations do not reach mature levels until 5–7 years of age, and intracortical fibers continue their myelination processes well into the third decade of life. Numerous morphological studies demonstrate that the corpus callosum is uniformly thin in the first month postnatally. The genu and then the splenium undergo rapid growth spurts during the next 5 months, resulting in their characteristic "bulbous" appearance.

Cerebral Metabolic Rate Increases and then Decreases after Birth

Increases in neuronal activity have been linked to increases in cerebral metabolism, as measured by neuroimaging techniques. Data show substantial subcortical activation in newborns, notably in the thalamus and phylogenetically old portions of the cerebellum, but little activation of the cerebral cortex. However, over the first 3–4 years of life, cortical metabolic rate increases until it reaches levels twice those observed in adults. After 4 years of age, metabolic activity declines gradually to adult levels at around age 15. The time course of the rise and decline of activity, as revealed by positron emission tomography (PET), varies across cortical regions but parallels the rise and decline in the number of synapses in these areas, suggesting that the exuberant cortical synapses observed during development are metabolically active. As these synapses are eliminated, metabolic activity decreases.

Dorsolateral Prefrontal Cortex Is One of the Last Brain Regions to Develop

Refinement in the circuit organization of the dorsolateral prefrontal cortex, like that of the hippocampal formation (see earlier discussion), continues until quite late in development. In the case of the dorsolateral prefrontal cortex, a gradual decline in synaptic density continues well into late adolescence and suggests that connectivity

in this cortical region undergoes substantial change until 15–20 years of age. These changes are accompanied by a decrease in metabolic rate during the same period (Fig. 43.3). It is believed that changes in the neuromodulatory effects of dopamine may influence the adolescent refinement of excitatory and inhibitory inputs to layer III pyramidal neurons and that dopamine may have a particularly strong influence on cortical information processing around the time of puberty (for the relevance of this late prefrontal cortex development in the emergence of psychopathologic states, such as schizophrenia, see the section on pathological processes).

Summary

Structural, metabolic, and physiological indices of human brain development all point to a long postnatal time course that displays considerable variability from region to region and from system to system. Thus, while postnatal development in the hippocampus proceeds until approximately 4–5 years of age, it continues until 7–11 years for the visual cortex and until around 16 years of age for the frontal cortical areas. The dorsolateral portion of the prefrontal cortex appears to be one of the last regions of the brain to develop. Interestingly, the development of myelin has been observed as late as the third to fourth decade of life for fibers within the association areas of the neocortex. Finally, brain structure, size and developmental trajectories are sexually dimorphic.

COGNITIVE DEVELOPMENT AND AGING: A LIFE SPAN PERSPECTIVE

Investigators are now attempting to link the types of neural changes described in the preceding section to the maturation of sensory, behavioral, and cognitive capacities in infants and children. Such studies are limited in number. Until recently, the predominant view was that postnatal development of the cortex is largely intrinsically determined. However, new studies of both animals and humans have revealed a central role for extrinsic factors in shaping the organization of neural systems and in permitting recovery from brain damage. Indeed, calculations showing that information in the genome is not sufficient to specify the connectivity of the brain, together with evidence for the long-lasting existence of transient, redundant connections in primates, suggest that neural changes under the influence of environmental input play a significant and persistent role in the development of functional specificity in the human brain. Thus, genetic and environmental influences are intimately intertwined in guiding brain development (Lenroot et al., 2009).

Cognitive Development in the First Years of Life

Anatomical Development of the Visual System in Infants Is Linked to Functional Development

Several parallels have been noted between anatomical changes and the emergence of visual system function in humans. The visual abilities of the newborn have been linked to subcortical structures that show mature anatomy and high metabolic rates during this period. The limited visual abilities of the newborn are augmented by the appearance of smooth pursuit tracking around 6–8 weeks. The emergence of this capacity may be related to the maturation of cortical layers IV, V, and VI in V1 (Fig. 43.2). These layers connect magnocellular afferents from the lateral geniculate nucleus and the middle temporal (MT) region, a pathway important for the detection of visual movement. Visual acuity and visual alertness increase dramatically around 4 months of age, when the volume of visual cortex reaches adult levels and the highest density of synapses is present. Shortly thereafter, cortically mediated binocular interactions become apparent. These interactions, which include stereoacuity, binocular summation of the light reflex, and stereopsis (binocular depth perception), appear in the same time frame as maturation of the middle cortical layers and rapid synaptogenesis in V1. This period of rapid growth appears to be a time of increased vulnerability to altered afferent input. Strabismic amblyopia and amblyopia due to the absence of patterned input (i.e., centrally mediated visual impairments) are reported to occur at this age unless corrected early. The time period during which visual impairments can be corrected is different for different visual functions. For example, correction for an absent lens (aphakia) due to cataracts may be completely effective only when performed prior to 2 months of age—that is, just prior to the onset of exuberant synaptogenesis in V1. However, very high synaptic density persists to at least the age of 4 years in V1. The presence of this extensive connectivity may account for the ability to recover from amblyopia (with forced use of the strabismic eye) during this time. If the disruption of binocular convergence by strabismus is not corrected within the first year of life, the ability to see stereoscopically may not develop even though the development of acuity and contrast sensitivity is normal. Thus, there may be separate critical periods (see Chapter 21) for the development of resolution acuity and stereopsis. Because the parvocellular system is thought to underlie acuity, whereas disparity detection is mediated by the magnocellular system, the magnocellular system may be more modifiable by environmental input than the parvocellular system. This differential sensitivity may be due to the slower maturation of the magnocellular system and/or to differences in the number of exuberant synapses within these systems.

Studies of individuals born deaf and blind suggest that in humans, as in other animals, there is a time period when cortical areas that normally process information from the deprived modality can be reorganized to process information from intact modalities. From the alteration of visual functions seen in individuals born deaf, it appears that areas of the auditory cortex have been recruited for visual function. Deaf subjects, by comparison, show abnormally strong electrical responses to peripheral visual stimuli. These responses are not found in normally hearing individuals, even those exposed to sign language by deaf parents. The prolonged persistence of exuberant cortico-cortico connections may provide the substrate for such cortical reorganization.

Development of the Ventral Visual Stream and Object Representation

A multitude of visual cortical areas located in the striate and extrastriate cortex contribute to different aspects of visual processing (see Chapter 44). These visual areas have been divided into two visual processing systems, one coursing ventrally from the striate and extrastriate areas to the ventrolateral temporal cortex and the other coursing dorsally from the striate and extrastriate cortex to the parietal cortex. The dorsal stream mediates spatial processing associated with attention to movement and location, whereas the ventral stream is involved primarily in processing information about patterns and objects. Both streams project rostrally, each reaching common and adjacent areas of the prefrontal cortex.

Major functions of the ventral stream include the ability both to segment a pattern into a set of constituent parts (local level of processing) and to integrate those parts into a coherent whole (global level of processing). In adults, systematic differences exist in the distribution of global and local levels of processing within the brain, such that global levels of processing are associated with the right posterior temporal region and local levels of processing with the left posterior temporal regions. Around 4 months of age, infants show hemispheric differences for global and local processing that are similar to adults. Thus, at this age, children segment out well-formed units and use simple associations to organize these units into a configuration. With further maturation, children show changes in the way they decompose objects into parts and in the relations they use to organize the parts. These changes may reflect the protracted development of the posterior temporal cortical areas, a finding consistent with ERP studies in human infants indicating functional activation within the temporal cortical areas around 6 months of age. The latter observation parallels the emergence, around the same age, of object representation and visual rule learning (Alvarado & Bachevalier, 2000).

Development of the Dorsal Visual Stream and Spatial Attention

A variety of spatial processes have been associated with activation of the dorsal visual pathway, such as the processing of information about spatial attention and spatial location (see Chapter 45). Considerable clinical and experimental evidence shows that the posterior parietal lobe plays a crucial role in the ability to shift attention to different spatial locations. By at least 6 months of age, infants, like adults, show facilitated stimulus detection as a function of prior cueing—that is, they take less time to detect an object if it is presented at a location that has been cued previously. They also demonstrate, as do adults, quicker target detection when the interval between the cue and target is short than when this interval is long. While this basic attentional response may be robust as early as 4 months of age, the timing parameters that elicit the response change with development, suggesting that further maturational processes occur in the parietal cortex.

Precursors of Declarative Memory Emerge Early in Development

Looking preference has been used to study the emergence of recognition memory ability in both human infants and monkeys (Bachevalier & Vargha-Khadem, 2005). In both species, the most common procedure is to first present the infant with an attractive stimulus for a period of time (generally 20 to 30 s). After an intervening delay that can vary from a few seconds to many hours, the familiar stimulus is shown together with a new item. Human infants as young as 1 day old display a strong preference for looking at the novel object after delays as long as 24 h, demonstrating that they recognize the previously presented item as familiar. The early emergence of recognition memory is also observed in infant monkeys and, in this species, surgical removal of the hippocampal formation and adjacent tissue before the age of 3 weeks disrupts this ability only when the hippocampus normally becomes fully mature (around 1 year of age in monkeys). Thus, early developing recognition memory processes are likely mediated by allocortical areas (phylogenetically older cortex) of the medial temporal lobe, such as the perirhinal cortex and parahippocampal gyrus. These cortical areas are known to develop earlier than the hippocampus (Zeamer & Bachevalier, 2010). The capacity for recall over long periods of time, as measured by nonverbal deferred imitation tasks, also emerges by the end of first year in humans and is impaired after early hippocampal injury (Bauer, 2002; de Haan, Mishkin, Baldeweg, & Vargha-Khadem, 2006).

The early emergence and continued improvement of recognition and recall abilities is consistent with what is known about maturation of the hippocampal formation in both humans and monkeys (see earlier discussion). In both species, the hippocampal formation is almost

adult-like at birth, although there are a number of postnatal morphological refinements that continue until the end of the first year in monkeys and until about 4–5 years of age in humans. These protracted modifications in hippocampal circuitry, together with the further maturation of cortical areas in the temporal and prefrontal lobes, may provide a basis for the similarly late elaboration of certain capacities, including spatial and relational memory (see Chapter 48). Evidence that contributions of the medial temporal lobe and prefrontal cortex to declarative memory follow distinct developmental trajectories has also been documented by functional neuroimaging (Ofen et al., 2007).

Orientation to Faces, Recognition of Mother's Face, and Imitation of Facial Expressions Are Present at Birth

The human face is a powerful visual source of social information, and the development of face-processing abilities appears to follow a delayed postnatal development. Newborns preferentially orient to faces, recognize the mother and other familiar faces, and imitate facial expressions. These precocious tendencies appear to be mediated by a subcortical retinotectal pathway. For example, newborns display preferences selectively for moving stimuli presented in the peripheral visual field (i.e., under conditions that engage the subcortical systems), but not when they are displayed in the central visual field.

The fact that newborns just hours to days after birth look longer at the mother's face than at a stranger's (even when cues from her smell and voice are eliminated) indicates that, from very early on, there is a mechanism capable of learning about individual faces based on experience. This early learning system may be mediated by early developing allocortical areas known to be involved in memory (see earlier discussion; Shaw et al., 2008). Nevertheless, the face-processing abilities of the newborn are qualitatively different than the sophisticated capacities of adults, and none of these tendencies are necessarily the direct precursors of the cortically mediated, adult face-processing system (see Chapter 44). Instead, these responses might serve the purpose of providing input to developing cortical circuits that will at some later time functionally emerge to mediate face processing.

At 3 Months of Age Infants Are Able to Form Categories of Visual Stimuli

A marked change in infants' visual attention to faces occurs at approximately 8 weeks of age. At this time, infants' preferential following of peripheral moving faces declines, and a preference emerges for fixating faces compared to other patterns presented in the central visual field. This behavioral change is thought to be due to the functional development of visual cortical pathways that inhibit the preferential following response and mediate the new preferential fixation response. At 2 months of age, infants become more sensitive to the internal facial features of static faces. In addition, within the face, the eyes are a more salient feature than the nose or mouth, but where the eyes are located is immaterial to the babies' preference for face-like drawings. At roughly the same age, infants begin to relate information between individual faces and to form categories; that is, they perceive visual stimuli with comparable features as being more similar than visual stimuli with different features. They also exhibit inversion effects (i.e., recognition of upright faces is easier than recognition of inverted faces). The change between 1 and 3 months has been associated with the functional development of temporal cortical areas and their connections with the hippocampus and adjacent structures. However, at this early age, the change may not be specific to faces, as 3-month-old infants can form perceptual categories of a variety of other complex categories, such as tables and trees.

During childhood, the child's prototype of the face becomes more tuned to the types of faces that the child sees most often, and with this may emerge race effects and other species effects seen in adult face processing. Other race effects refer to the ability to distinguish among faces of one's own race more quickly than faces of other races. Other species effects refer to the ability to distinguish between human faces more quickly than faces of other species. These last changes may be based on experience due to increased exposure to faces, the number and type of features children attend to and encode, and the maturation of a posterior temporal cortical area (the fusiform area) that is known to be involved in face processing in adults.

Fear of Unfamiliar Faces Emerges between 7 and 9 Months

Although infants are able to discriminate among some facial expressions of emotion by 3 months of age, they do have difficulty discriminating between sadness and surprise. It is only by 7 months of age that infants, like adults, show categorical perception of facial expressions. For example, with pictures of faces in which emotional expressions are progressively degraded from happy to fear, human infants and adults exhibit more accurate discrimination for pictures of faces that cross emotional categories (happy versus fear) than for pictures of faces within the same emotional category, despite equal physical differences in the pictures. With this increased ability to categorize faces, and the increased exposure to familiar faces, two remarkable events occur between 7–9 months of age: the emergence of fear for unfamiliar people and anxiety during temporary separation from the caretaker. Distress under both conditions must involve more than

the ability to discriminate strangers from parents because 3 month-olds can make this discrimination, but do not show fear reactions.

One speculation concerning stranger and separation fear is that improvements in working memory, and an enhanced ability to retrieve memories of a past event, are required for the appearance of these reactions. This change appears to be associated with the maturation of the orbital frontal cortex (Schore, 1996), a region of the prefrontal cortex intimately interconnected with limbic areas in the temporal lobe (temporal pole cortex and amygdala), with subcortical drive centers in the hypothalamus, and with dopamine neurons in reward centers in the ventral tegmental area. By the end of the first year, the initial phase of orbital frontal maturation is achieved and allows for developmental advances that enable the individual to react to situations on the basis of stored representations, rather than on information immediately present in the environment. In the case of the orbital frontal cortex, this capacity applies specifically to socioemotional information. Indeed, by 10 months, infants are first able to construct and store abstract prototypes of human visual facial patterns, and can use these prototypes to evaluate novel information.

In an illuminating experiment, a preferential looking task was used to habituate 10-month-old infants to pictures of faces. One condition presented faces of different females, and in the other condition, the same female face was presented in various poses. After infants habituated to the stimuli (i.e., decreased their looking), they were given two test trials: one with a face of a familiar female and another with a face of a novel female. When infants were previously habituated using different female faces, they spent equivalent amounts of time gazing at familiar and novel faces on the test trials. However, when infants were habituated to the same face with different poses, they generalized their looking response to the familiar face but dishabituated (or looked longer) at the novel face. This pattern of results suggests that infants can abstract relevant categorical information by 10 months of age.

Changes in Visual Search Are Related to Development of the Prefrontal Cortex

Infants younger than 7 or 8 months of age will not uncover a hidden object. If a cloth is thrown over a toy while an infant of 5 or 6 months is reaching for it, the infant will withdraw his or her hand and stop reaching. By 7 or 8 months, most infants who watch an object being hidden can retrieve it. However, if the infant then watches as the object is hidden at a second location, most infants of 7–8 months search for the object at its first hiding location, which is now empty. Jean Piaget called this the A-not-B error because the infant is correct at the first hiding place (A) but not at the second (B). It is rare to see this error when there is no delay between when the object is hidden and when the infant is allowed to reach. However, a delay as brief as 1, 2, or 3 s is sufficient to produce the error in infants 7–8 months of age. As they grow older, the error is still seen, but only if the delay between hiding and retrieval is increased. The A-not-B error suggests that during the second half of the first year the brain has matured sufficiently to enable the infant to hold a representation of the object's location in mind (working memory) for a few seconds (see Chapter 50) or to understand the relationship of (a) their previous action of retrieving the object, (b) the subsequent hiding of the object in a different location (even though they observed the hiding), and (c) the object's present whereabouts (Diamond, 1990). The enhanced working memory observed in the 7- to 10-month-old infant parallels the protracted maturation and refinement of dorsolateral prefrontal cortex circuitry (Fig. 43.3). After 12 months of age, it is difficult to elicit the A-not-B error.

Language Undergoes Rapid but Prolonged Development

In humans, the prolonged structural, metabolic, and neurophysiological maturation of "association" cortical areas, which continues well into adolescence, provides the substrate for the panoply of higher cognitive functions that continue to develop during this time. Attempts have been made to link the very rapid development of speech and language skills over the first 3 years of life to these general changes. This goal has remained elusive, probably because so many aspects of the brain and behavior are changing together. Moreover, key elements of language appear to be processed at cellular and synaptic levels of organization that are difficult to investigate in humans with even the most sophisticated techniques available.

There is wide agreement that language is strongly dependent on structures within the left perisylvian region (see Chapter 49). Very early on (by 28 weeks of gestation), structural asymmetries appear between the temporal lobes; these may provide the substrate for the functional asymmetries that appear later. The rapid and early acquisition of phonological information and speech production and comprehension, and the subsequent burst in size of the vocabulary, may be linked to the rapid rise in the number of synapses and the marked increases in cortical metabolism that occur during the second year of life. Also, the persistence of large numbers of exuberant synapses through adolescence may provide the anatomical substrate for prolonged neural plasticity and recovery of language skills following cortical damage in the first decade of life. It is well established that language skills can display considerable recovery following large lesions involving the left hemisphere during the first 7–10 years of life.

The impressive language recovery in children who have undergone left hemisphere removal is even more striking in light of the enduring impairment seen in specifically language-impaired children or the reading difficulties encountered by dyslexics, in whom macroscopic aspects of brain structure are basically normal. These findings underscore the importance of characterizing microscopic structural aspects of the brain and the functional organization of the brain in relation to processing.

The prolonged time course of development that may confer plasticity on the immature brain appears to be characterized by optimal or critical periods (see Chapter 21) for language acquisition. Several studies report that both first and second language acquisitions are impaired, and cerebral organization is altered, when language is acquired after the first decade of life. Moreover, as has been observed for vision (Fig. 43.2), different aspects of language appear to display different critical periods. Vocabulary items can be acquired long past the first decade of life, but the grammatical rules of a language appear to be acquired most readily before the age of 10. Along with other evidence, this pattern suggests that different neural systems, with differing developmental time courses, mediate these various aspects of language.

Summary

Cognitive development parallels some of the most important changes in brain development. Thus, the visual abilities of the newborn are limited and control by subcortical systems predominates. With the maturation of visual cortical areas in the first few postnatal months, visual acuity, visual alertness, and stereopsis develop. With further development of visual cortical areas within the temporal lobe, an infant's ability to recognize faces using internal facial features, mostly the eye region, emerges around 3 months of age. However, it is only by 7–9 months of age that infants develop fear of unfamiliar people. It is believed that this behavior is associated with the development, around this age, of the orbital frontal cortex, a cortical area that enables the infant to react to situations on the basis of stored representations (working memory). The enhanced spatial working memory abilities observed by the middle of the first year parallel the protracted maturation and refinement of the dorsolateral prefrontal circuitry. Finally, the maturation of association areas of the cortex, which continues well into adolescence, provides the substrate for the development of higher cognitive functions, such as language. In the future, it will be possible to analyze the neural basis of cognition in increasing detail by using high-resolution methods for imaging brain structure and function in normally developing children and children with specific structural or functional deficits.

COGNITIVE AGING

Average Human Life Expectancy has Increased Dramatically

The world's population is growing older. Whereas life expectancy in the United States was approximately 50 years in 1900, infant mortality rates decreased dramatically during the last century, and combined with advances in disease prevention and treatment, current life expectancy is approaching 80 years in many industrialized countries. A significant demographic trend is that the percentage of the population over 65 years of age is projected to more than double between the years 2000 and 2030, with particularly rapid growth among those over 85. Neurodegenerative disorders such as Alzheimer's disease are among the most devastating consequences of growing older (see section on Dementia, this chapter). There is increasing recognition, however, that many otherwise healthy aged individuals experience deficits in memory and other aspects of cognitive function that, although less severe, pose a significant risk to independence and the quality of life. The following sections outline key concepts from the study of normal cognitive aging in the absence of frank disease.

Effects of Normal Aging on Memory Are Variable

Cognition encompasses a variety of dissociable capacities, including perception, attention, executive function, and memory (Section VII, this volume), mediated by partially distinct neural systems. On the basis of this organization, neuropsychological research documenting the specific types and severity of cognitive deficits that accompany aging can provide important clues about the brain systems that mediate dysfunction. This strategy has been widely exploited to examine the effects of normal aging on learning and memory, where a rich background is available concerning the characteristics of impairment that follow damage to selective brain regions in young adults.

A key concept to emerge from neuropsychological studies of aging is that the status of memory mediated by the hippocampal formation and related medial temporal lobe structures varies substantially among older individuals (Fig. 43.4). In humans and animal models, memory ability is continuously distributed across a broad range such that some aged individuals exhibit considerable impairment while others—at the same chronological age—perform as well as young adults. Long considered a complicating factor in gerontological research, this variability suggests the important conclusion that marked deterioration in memory is not an inescapable consequence of growing older and that the functional integrity of the medial temporal lobe system is preserved in a substantial proportion of aged individuals. The next section considers findings

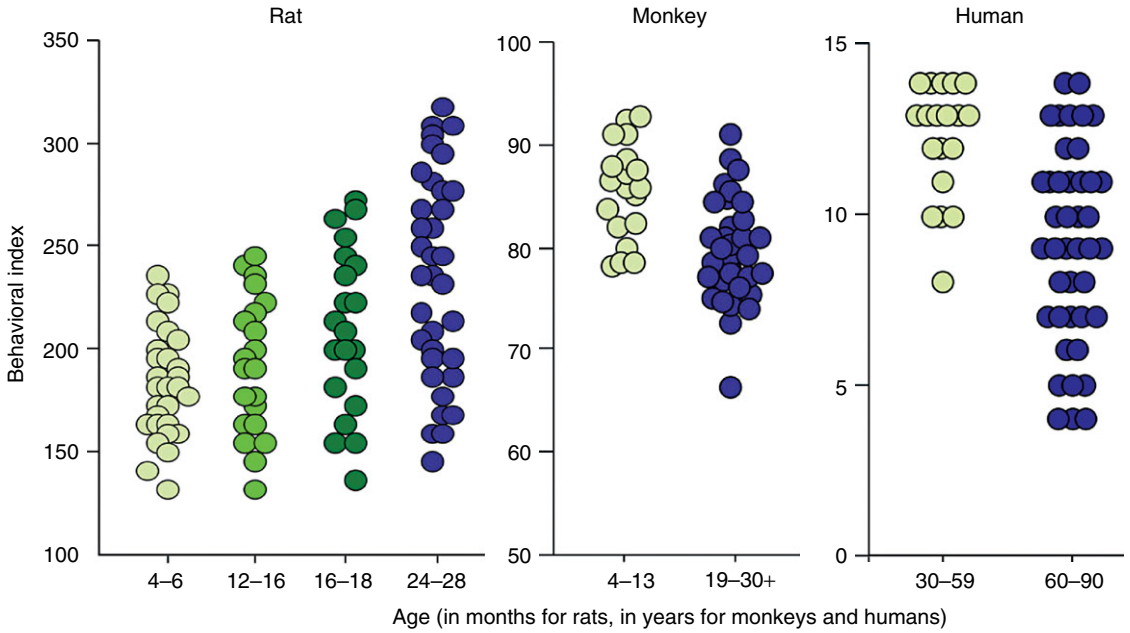

FIGURE 43.4 The status of memory varies considerably across aged individuals. The data comprise a summary measure of spatial memory in rats (courtesy of M. Gallagher, Johns Hopkins University), object recognition memory in monkeys (courtesy of P. Rapp, National Institue on Aging), and delayed recall in humans (courtesy of M. Albert, Johns Hopkins School of Medicine). For rats, low scores represent better memory, and high values reflect better performance in monkeys and humans. Symbols signify scores for individual subjects. Note that in all species the status of memory among the aged is distributed across a broad range, from individuals that score on a par with the best young adults to other individuals that exhibit substantial impairment.

from animal models supporting this perspective, and that have guided efforts to identify the neurobiological alterations reponsible for individual differences in normal cognitive aging.

Animal Models of Normal Neurocognitive Aging

As described in Chapter 48, normal adult rats solve the spatial, or "place," version of the Morris water maze by learning and remembering the escape location in relation to cues surrounding the testing apparatus, and this capacity requires the hippocampal formation. Guided by this background, many laboratories have used the Morris water maze and other spatial tasks to examine the effects of aging on learning and memory mediated by the hippocampal system (reviewed in Rosenzweig and Barnes, 2003).

Aged rats learn the hidden platform location in the place version of the water maze more slowly than young adults. Although these findings are consistent with a possible hippocampal contribution to cognitive aging, an alternative account is that declining visual acuity, motor function, or other impairments give rise to performance deficits in older subjects. This possibility has been tested using control procedures that make many of the same sensory, motor, and motivational demands as the hidden platform task, but that lack an explicit spatial learning component. In a common task variant, for example, rats swim to a platform that protrudes above the surface of the water, providing a salient visual goal to guide navigation. Because the cued platform location is varied randomly across trials, learning and memory for spatial information are not required. Many aged rats acquire this task normally, demonstrating that they can swim proficiently, are motivated to escape, and retain sufficient visual acuity to support accurate cue-directed navigation. Thus, whereas some aspects of motor and visual function are indeed vulnerable to aging, these impairments fail to explain the deficits aged rats exhibit in the spatial version of the water maze. Instead, the overall profile observed in aging—impaired spatial learning and memory against a background of intact goal-approach learning—is qualitatively similar to the effects of damage to the hippocampal system in young subjects. Other tasks that require hippocampal integrity are also sensitive, confirming that learning and memory mediated by this system are susceptible to age-related decline (Rosenzweig & Barnes, 2003).

As noted earlier, research in animal models has revealed substantial individual variability in the cognitive outcome of aging. Figure 43.4, for example, illustrates individual learning scores for large numbers of young, middle-aged, and aged rats tested in the spatial version of the water maze. The performance measure in this case reflects distance from the escape platform, averaged over multiple trials, and accordingly, low scores represent better learning, with searching focused near the escape

location. Similar to the distribution of memory scores for people (Fig. 43.4), spatial learning capacity among aged rats varies across a broad range such that some perform as well as even the most proficient young subjects. By comparison, approximately half of the older animals exhibit marked deficits, scoring outside the range of the young adult group.

Variability in the cognitive effects of aging has been examined in nonhuman primates as well, taking advantage of testing procedures adopted from studies on the effects of medial temporal lobe damage in young adult monkeys (see Chapter 48). In the delayed nonmatching to sample task, subjects are tested for their ability to recognize a visual stimulus after a delay ranging from seconds to many minutes or more. Monkeys with sufficiently extensive damage to any component of the medial temporal lobe memory system display significant deficits on this task, particularly under conditions of increased memory demand, with long retention intervals. Recognition memory declines during aging in the monkey, and as in humans and rats, the degree of impairment varies substantially across individual subjects (Fig. 43.4). As discussed in the next section, this variability makes it possible to ask what neurobiological alterations distinguish the brains of individuals with age-related memory impairment from other, age-matched subjects with preserved function. The aim by this approach is to identify changes in the structure and physiology of the aged brain that are specifically coupled to individual differences in the cognitive outcome of normal aging.

Neurobiology of Age-Related Memory Decline

Age-Related Learning and Memory Impairment Is Associated with Compromised Hippocampal Physiology

Behavioral studies suggest that the functional integrity of the hippocampal system declines during aging. Electrophysiological investigations extend these observations by directly assessing the computational processing functions of the aged hippocampus. Models of learning-related cellular plasticity, such as hippocampal long-term potentiation and depression (LTP and LTD; see Chapter 47), establish a useful background against which to explore the effects of aging. A prominent theme is that aging influences hippocampal physiology in a highly selective manner, sparing many aspects of function (reviewed in Burke and Barnes, 2006: and Wilson, Gallagher, Eichenbaum, and Tanila, 2006). Parameters that exhibit little or no change in older subjects include the resting potential, input resistance, and the amplitude and duration of evoked action potentials of principal hippocampal neurons. By comparison, although the peak magnitude of LTP is comparable in the young adult and aged hippocampus, the intensity and frequency of stimulation necessary to achieve that response increase with advanced age. Once established, LTP also decays to prepotentiated baseline levels more rapidly in aged subjects than in young animals. This enhanced rate of decay is correlated with the rapid forgetting aged rats exhibit on tests of spatial memory, consistent with the conclusion that a reduced capacity for synaptic enhancement in the hippocampus contributes to this behavioral deficit. Hippocampal LTD is also affected, demonstrating that multiple plasticity mechanisms are altered in relation to variability in the cognitive outcome of aging.

Electrophysiological studies of ongoing neuronal activity in awake-behaving rats provide a direct window on how normal aging influences hippocampal information processing. As described in Chapter 48, a particularly well-characterized phenomenon is that the firing rate of individual pyramidal neurons in the hippocampus increases dramatically as animals navigate through a restricted area within a testing environment. This "place field" activity is largely independent of the specific behaviors that accompany exploration and instead reflects the cognitive demands of testing in relation to sensory cues that define a particular spatial location. Recapitulating a theme from studies of LTP and LTD, many aspects of place field firing are unchanged in the aged hippocampus, including the percentage of neurons that exhibit location-specific firing, and the spatial selectivity of place fields. The overall scope of information encoded, however, is reliably altered (Burke & Barnes, 2006; Wilson et al., 2006). For example, hippocampal pyramidal cells in old rats are abnormally prone to confuse familiar environments that include overlapping stimulus elements, unpredictably engaging the wrong distribution, or "map," of place fields during successive bouts of exploration in a given setting. Hippocampal encoding also becomes increasingly rigid with age such that a relatively narrow subset of available spatial cues comes to control place field activity. These changes are more prevalent in the CA3 field of the hippocampus than in CA1, and among aged individuals that demonstrate impaired spatial learning (Wilson et al., 2006). Research on the structural integrity of the hippocampus, discussed in the following sections, points to a potential link between the behavioral and electrophysiological consequences of aging.

Early Findings Suggested Neuron Loss Is Distributed Diffusely throughout the Aged Brain

One of the most widely held notions about brain aging is that substantial numbers of neurons inevitably die as we grow older. Early studies supported this view, suggesting that neuron death occurs throughout life, with the cumulative loss exceeding 50% in many neocortical areas by age 95 (for an historical review, see Brody, 1970). Although the magnitude of effect appeared to vary, significant

age-related neuron loss was reported for all regions examined, including both primary sensory and association areas of the cortex. On the basis of these early observations it seemed reasonable to suppose that widely distributed neuron death might account for many of the cognitive deficits associated with normal aging. A significant concern, however, was that the finding of widespread neuronal loss might be attributable to preclinical dementing disease in an unknown proportion of the aged individuals who were examined. This confound is overcome in studies using animal models of cognitive aging because rats and monkeys do not develop dementia spontaneously. In addition, as described next, improved quantitative tools for examining neuron loss in the aged brain are now widely available.

Memory Impairment during Normal Aging Does Not Require Substantial Hippocampal Neuron Loss

Methodological developments in quantifying cell number have prompted significant revision in traditional views on age-related neuron loss (Morrison & Hof, 1997). Before the 1990s, most investigators focused on cell density, defined as the number of neurons present in a fixed area or volume of tissue. A significant limitation, however, is that density can vary widely in the absence of any actual difference in cell number. Assume, for example, that total neuron number is identical in two brains, but that the overall size of the brains differs due to normal biological variability among individuals, gliosis, white matter abnormalities, or other neuropil alterations. Under these conditions, neuron density will be lower in the larger brain, simply as a consequence of the cells being distributed in a larger volume. In this way, real or processing-related volumetric differences between young and aged brains could substantially influence cell density in the absence of any actual age-dependent difference in neuron number.

The field of stereology has provided standardized tools for quantifying total neuron number in any defined brain region, yielding an unequivocal measure for examining potential neuron loss during normal aging (see Box 43.1). In contrast to early studies measuring cell density, the conclusion from investigations using modern stereological methods is that the total number of principal neurons (i.e., granule cells of the dentate gyrus and pyramidal neurons in the CA3 and CA1 fields) is preserved in the aged hippocampus. Substantial sparing is also seen in adjacent parahippocampal cortical regions that critically participate in memory. Whereas similar results have been observed in humans, data from animal models are particularly illuminating in demonstrating that hippocampal neuron number remains stable even among aged individuals with pronounced learning and memory deficits. As illustrated in Figure 43.5, for example, stereological analysis reveals that the total number of neurons comprising the hippocampal region is comparable in young adult subjects and aged rats, regardless of their capacity for spatial learning and memory.

The dentate gyrus of the hippocampus is one of only a few niches of neural stem cells capable of generating new neurons in the adult brain (see Box 14.1). Whereas diffuse neuron death is no longer considered a prominent feature of normal aging, considerable interest centers on the idea that a decline in hippocampal neurogenesis contributes to cognitive aging, and that interventions designed to enhance neurogenesis might protect against age-related memory decline, or even rescue function in Alzheimer's disease. Although neurogenesis rates decrease precipitously in the adult rat hippocampus, this effect emerges much earlier in the lifespan than age-related deficits in hippocampal memory, and it fails to predict individual variability in the severity of impairment (reviewed in Bizon and Gallagher, 2005). Considerable additional study will be needed in order to fully exploit neural stem cell biology in support of healthy cognitive aging.

Hippocampal Connectivity Is Compromised during Normal Aging

Substantial research has focused on changes in synaptic connectivity and other markers of functional deterioration as potential contributors to normal cognitive aging. The entorhinal cortex originates the major source of cortical input to the hippocampus, giving rise to the so-called perforant path, which synapses on the distal dendrites of dentate gyrus granule cells in outer portions of the molecular layer. The same entorhinal cortex neurons also innervate other fields of the hippocampus, including the most distal aspects of CA3 pyramidal cell dendrites. Multiple lines of investigation suggest that the integrity of these inputs is compromised with age. Stereological quantification of electron microscope images, for example, has documented that aging is associated with significant loss among a morphologically distinct subset of synapses in the outer molecular layer of the dentate gyrus (i.e., the zone innervated by the entorhinal cortex) (Geinisman, de Toledo-Morrell, Morrell, Persina, & Rossi, 1992), together with alterations of synaptic structure (e.g., descreased postsynaptic density length) in other hippocampal subfields. Input originating in the entorhinal cortex conveys much of the neocortically derived information that the hippocampus processes in support of normal memory, and accordingly, it is reasonable to suppose that the disruption of entorhinal–hippocampus connectivity might contribute to the cognitive outcome of aging. Consistent with this proposal, the magnitude of morphological alterations observed in the hippocampal termination zones of the entorhinal cortex is greatest among aged animals with documented deficits on tasks that require the hippocampus and among older rats that exhibit abnormalities in various physiological measures of hippocampal plasticity.

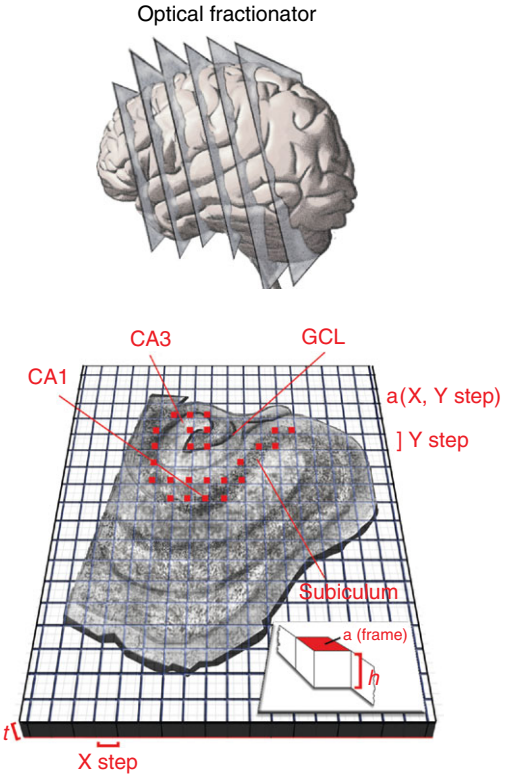
BOX 43.1

THE OPTICAL FRACTIONATOR STEREOLOGICAL METHOD

The figure shows the key features of a stereological technique designed to provide accurate and efficient estimates of total neuron number in a brain region of interest. The hippocampal formation is used as an example. The method consists of counting the number of neurons in a known and representative fraction of a neuroanatomically defined structure in such a way that each cell has an equal probability of being counted. The sum of the neurons counted, multiplied by the reciprocal of the fraction of the structure that was sampled, provides an estimate of total neuron number.

Serial histological sections are prepared through the rostrocaudal extent of the hippocampus and are stained by routine methods for visualizing neurons microscopically. An evenly spaced series of the sections is then chosen for analysis (positions represented schematically in top panel). This first level of sampling, the "section fraction," therefore comprises the fraction of the total number of sections examined. For example, if every tenth section through the hippocampus is analyzed, the section fraction equals 1/10. The appropriate sections are then surveyed according to a systematic sampling scheme, typically carried out using a microscope with a motorized, computer-controlled stage. The lower part of the figure illustrates this design in which the microscope stage is moved in even X and Y intervals, and neurons are counted within the areas defined by the small red squares ("a (frame)" in the inset). The second level of the fractionator sampling scheme is therefore the "area fraction," or the fraction of the XY step from which the cell counts are derived.

The last level of sampling is counting cells only within a known fraction (h) of the total section thickness (t), avoiding a variety of known errors introduced by including the cut surfaces of the histological preparations in the analysis. This is accomplished using a high-magnification microscope objective (usually 100X) with a shallow focal depth. In the illustration provided, the "thickness fraction" is defined as h/t. Neurons are counted as they first come into focus, according to an unbiased counting rule, called the "optical



disector," that eliminates the possibility of counting a given cell more than once.

Finally, total neuron number in the region of interest (N) is estimated as the sum of the neurons counted (sumQ–), multiplied by the reciprocal of the three sampling fractions; the "section fraction," "area fraction," and the "thickness fraction." For the present example, the total estimated neuron number is given by

$$N = (\text{sumQ}-) \times (10/1) \times (\text{XY step area/a(frame)}) \times (t/h).$$

Executive Function Mediated by the Prefrontal Cortex Declines during Normal Aging

Normal aging is sometimes characterized as a generalized process of nonspecific deterioration across many neural systems, implying that age-related cognitive decline might be the cumulative effect of subtle alterations distributed diffusely throughout the brain. Little empirical evidence actually supports this notion, however, and as we have seen in the case of hippocampal circuitry, the current perspective is that the neurobiological consequences of aging exhibit considerable selectivity. At the same time, it is important to recognize that the effects of aging on memory do not occur in isolation and that cognitive capacities mediated by other neural systems are also vulnerable.

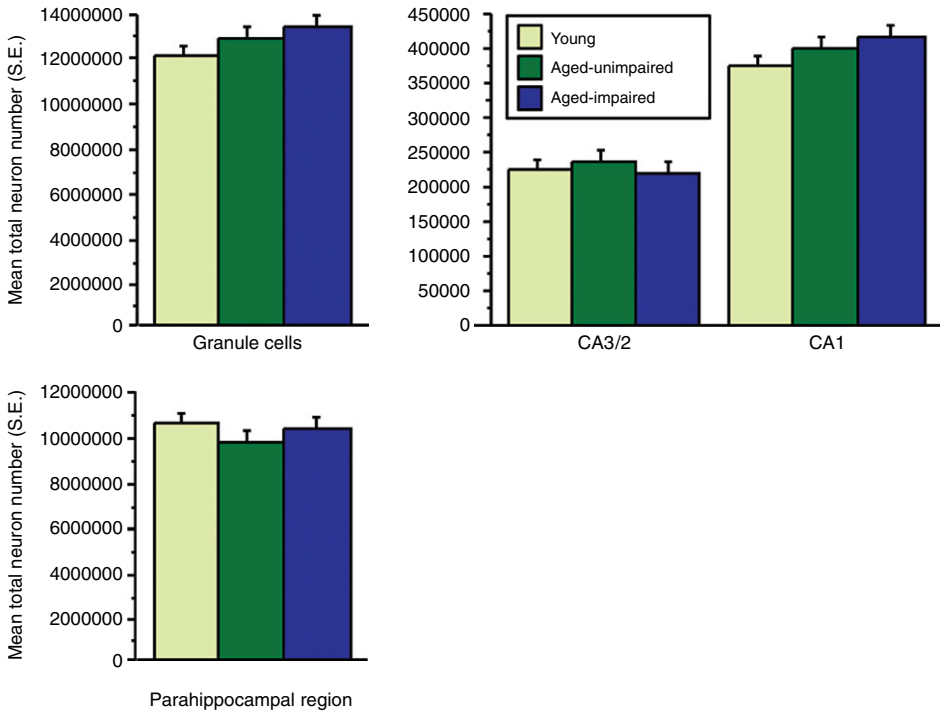

FIGURE 43.5 Estimated total neuron number (plus S.E.) in principal cell layers of the hippocampus and parahippocampal cortices (i.e., entorhinal, perirhinal, and postrhinal) for behaviorally characterized young and aged rats. All values are unilateral. Half of the aged rats exhibited substantial spatial learning deficits in the Morris water maze (aged impaired); the other half performed within the range of learning scores for the young group (aged unimpaired). Neuron number is stable with age and across a broad range of learning capacities. *Adapted with permission from Rapp and Gallagher (1996) and Rapp, Deroche, Mao, and Burwell (2002).*

As discussed in Chapter 50, the functionally and neuroanatomically heterogeneous areas comprising the prefrontal cortex support a constellation of capacities referred to as "executive function." Whereas damage to these regions does not produce the frank amnesia that follows medial temporal lobe lesions, significant deficits are observed in a variety of processing functions that influence memory, including the strategic use and manipulation of remembered information, the ability to recall the source from which information was acquired, and the order in which it was presented. It is therefore of interest that a qualitatively similar profile of deficits emerges during the course of normal aging (reviewed in Fletcher and Rapp, 2012). Older people, for example, often experience difficulty recalling the original source of remembered information, even when recollection of the target item itself is successful. These failures in "source memory" predict performance on other tests of frontal lobe function, including memory for temporal order, suggesting they share a common neurobiological basis.

Neuropsychological studies in animal models reinforce the conclusion that prefrontal cortex dysfunction contributes to certain features of cognitive aging. One of the best-documented deficits associated with aging in monkeys, for example, is poor performance under testing conditions that emphasize the spatial and temporal, or the "where and when," components of memory (Fletcher & Rapp, 2012). In the classic delayed response task, subjects observe while a food treat is hidden in one of two locations that are then covered with identical plaques (see Fig. 50.5). Because each reward location is baited frequently across trials within a single test session, there is substantial opportunity for interference and accurate performance depends on the ability to keep in mind the spatial location that was baited most recently. Damage involving the dorsolateral prefrontal cortex in young monkeys produces impairment on the delayed response procedure at retention intervals of just a few seconds or more. Deficits on this task following lesions of the hippocampal system, in contrast, are selectively observed at longer delays. Numerous studies since the late 1970s have documented that aged monkeys exhibit a profile of delayed response impairment qualitatively similar to the effects of prefrontal cortex lesions in young animals. Additional signs of prefrontal decline are also found in aged monkeys, including marked perseveration and behavioral rigidity when subjects are challenged with shifting task contingencies. For example, whereas young adults quickly cease responding to a previously positive stimulus when it is no longer rewarded, aged monkeys are slower to make this behavioral adjustment.

Are the effects of normal aging on prefrontal cortex capacities coupled to other signatures of cognitive decline, consistent with the view of aging as a process of generalized deterioration? Available evidence suggests that this is not the case. For example, age-related deficits on tests of prefrontal cortex function tend to emerge earlier during the course of aging than alterations in declarative memory supported by the medial temporal lobe system. In addition, when impairments indicative

of both frontal and medial temporal lobe dysfunction cooccur in the same subjects, these effects are statistically unrelated to each other (reviewed in Fletcher and Rapp, 2012). Thus, different aspects of cognitive function can decline independently during aging and these effects are not the consequence of a global, brain-wide degenerative process.

Neurobiology of Aging in the Prefrontal Cortex

The basis of age-related decline in capacities supported by the prefrontal cortex is the subject of intense investigation. Similar to the hippocampal system, neuron death is not a prominent feature of normal aging in many frontal lobe areas that mediate information processing functions known to decline with age. Other structural alterations have been documented, however, including a substantial decline in the density of prefrontal cortex synapses, marked changes in dendritic architecture, and a variety of abnormalities in the myelination of axons (Peters, Morrison, Rosene, & Hyman, 1998). These parameters are correlated with behavioral signatures of cognitive aging in monkeys, raising the possibility that, like the hippocampal system, changes in the functional organization of critical prefrontal networks may play a significant role. Consistent with this possibility, recent findings document that delayed response impairment in the aged monkey is associated with the blunting of memory-related neuronal activity in the dorsolateral prefrontal cortex, and that normal task dependent firing is at least partly restored by pharmacological treatments that benefit behavioral performance (Wang et al., 2011).

Results from *in vivo* imaging studies in humans complement the animal model data and further suggest that the functional organization of the aged brain is more dynamic than previously presumed. The traditional understanding has been that successful cognitive aging reflects the persistence of a youthful condition, dependent on the same mechanisms that support normal function in younger individuals. Rather than following a simple pattern of regional decline or maintenance, however, growing evidence indicates that aging is accompanied by reliable change in the distribution of activations across brain areas important for normal cognitive function, including the prefrontal cortex and medial temporal lobe. Indeed shifts in the balance of regional activation are observed even when memory is tested under conditions where aged individuals score as accurately as young adults. The implication of these findings is that the overall network engaged during testing is significantly altered and that successful cognitive outcomes in normal aging may rely, in part, on adaptive functional reorganization (reviewed in Hedden and Gabrieli, 2005). Intervention aimed at harnessing this dynamic capacity in support of optimally healthy cognitive aging is an area of active investigation.

Neurochemically Specific Subcortical Systems Are Susceptible to Aging and Positioned to Broadly Influence Behavior

Current evidence challenges the view that normal aging is associated with generalized deterioration distributed diffusely throughout the brain. Aging does, however, affect the integrity of neurochemically specific classes of cells whose ascending projections influence widespread brain areas. Cholinergic cell groups in the basal forebrain have been studied particularly intensively because this system exhibits pronounced degeneration in Alzheimer's disease. Less severe effects are also observed during normal aging, involving acetylcholine-containing neurons that project to the hippocampus, amygdala, and neocortex. Cholinergic cell loss might therefore disrupt the information processing functions of these target regions, and consistent with this possibility, reliable correlations have been reported between the magnitude of cholinergic deficits and behavioral impairment in aged individuals. Cholinergic abnormalities alone, however, fail to account for the full profile of cognitive deficits observed during aging since neurotoxin lesions that selectively destroy these neurons fail to reproduce key features of the behavioral decline observed in older individuals. One possibility is that age-related cholinergic impairment comprises an important component of a broader constellation of alterations that leads to cognitive dysfunction. Other neurochemical systems that might contribute include dopamine-containing circuitry that originates in midbrain cell groups and noradrenergic inputs that arise from the locus coeruleus. These systems innervate a variety of more anterior brain regions, and consistent with this broad distribution, neurochemical alterations have been linked to a diverse array of behavioral deficits ranging from age-related cognitive impairment to disturbances in motor function. These findings encourage the view that appropriately designed pharmacological interventions might have beneficial effects on a similarly broad profile of outcome measures of aging.

Summary

This section considered the cognitive and neurobiological effects of normal aging in humans and animal models. Key themes include the observation that the impact of aging on memory varies widely from one individual to the next. Whereas neuron death was once presumed to be the proximal cause of many cognitive deficits associated with aging, including learning and memory impairment, it is now clear that such decline does not require marked neuron loss in the hippocampus and related cortical areas. Instead, subtle alterations in connectivity, and downstream changes in cellular function, are more likely causative factors. Fueled by advanced *in vivo* brain imaging studies, a comprehensive, neural systems account of normal cognitive aging is beginning to emerge.

PATHOLOGICAL PROCESSES IN COGNITIVE DEVELOPMENT AND AGING

Developmental Psychopathologies

Research in this field focuses on elucidating the interplay among the biological, psychological, and social-contextual aspects of normal and abnormal development across the life span. Recent advances in neuroimaging and gene linkage technology have vastly expanded research possibilities for noninvasive clinical studies. Even with a new arsenal of research technologies, however, it has not been possible to isolate and define characteristics of each developmental disability. Such efforts are limited by several factors:

1. Disagreement regarding the criteria for diagnosis. Because different researchers often use differing behavioral criteria, cross-study comparisons frequently show inconsistencies in results.
2. Heterogeneity of disorders. Even when consistent behavioral criteria are carefully applied, different underlying etiologies can result in the same behavioral profile.
3. Difficulties inherent in the study of children. Although modern brain imaging techniques such as magnetic resonance imaging are considered noninvasive, they are stressful and time-consuming, and parents will not always allow their affected children to participate in such studies. Although studies can be conducted using adults who have been affected since childhood, data obtained from such studies may not accurately reflect anomalies that characterize the early disruption of brain development because brains change over time. Moreover, retrospective diagnoses of childhood disorders frequently rely on memory (e.g., a patient is asked, "Did you have difficulty reading as a young child?") and thus can be unreliable.

Despite these challenges, ongoing research has uncovered important neurological and genetic features that seem to be associated with specific developmental disorders (see Box 43.2). The following sections outline what is known about how specific injuries or anomalies in development of the brain may result in specific patterns of cognitive and behavioral impairment. Two examples of developmental psychopathology are described: autism and schizophrenia.

Autism

Autism is a neurodevelopmental syndrome first described by Kanner in 1943, characterized by deficits in multiple domains including social interaction, play, language, and communication, and a restricted range of interests and activities, including repetitive and stereotyopic movements and persistent preoccupation that begin in infancy and become more apparent by the end of the third year of life. Although autism was once considered a rare disorder, recent surveys report a prevalence of 40 to 50 per 10,000 births. Parents often first become concerned because their child fails to use words to communicate, even though he/she recites passages from videotapes or says the alphabet. Like other disorders of abnormal cognitive development, autism is a heterogeneous condition that can range widely in severity.

Characteristics of Autism

A multitude of symptoms occur in autism, including social isolation (the autistic child largely ignores other people, shows little attachment to parents or other relatives, and retreats into a world of his or her own); stereotyped behaviors (the autistic child rocks back and forth, stares at neutral stimuli, rotates an object, or engages in other repetitive behaviors for long, uninterrupted periods); resistance to change in routine; abnormal responses to sensory stimuli (the autistic child may ignore visual stimuli and sounds, especially speech sounds, sometimes to such an extent that it might be thought the child is deaf); inappropriate emotional expressions (the autistic child has sudden bouts of fear and crying for no obvious reason; at other times the child displays utter fearlessness and unprovoked laughter); and poor use of speech. Individuals with autism can also exhibit symptoms that fall along a continuum of disorders. For example, many have mental retardation and show delays in the development of language. Others display neither language delay nor mental retardation, although they are clearly socially inept. Finally, autism is also associated with idiosyncratic interests and a restricted and repetitive behavioral repertoire. A growing number of studies over the last two decades have provided evidence that autism results from early onset brain dysfunction.

Neuropathological Alterations in Autism

Several studies of autistic individuals provide evidence for megalencephaly (whole brain enlargement) and for increased head circumference. The nature of this enlargement has yet to be studied carefully, but it is specifically observed in the occipital, parietal, and temporal lobes. Postmortem analyses of the brains of autistic individuals have revealed increased cortical thickness and abnormalities in cortical morphology. Furthermore, abnormalities in the size and density of neurons in the medial temporal lobe and limbic system, including the amygdala, hippocampus, and entorhinal cortex, septal nuclei, and cingulate cortex, have also been documented. These neuropathological abnormalities make sense with respect to certain major symptoms of autism because the limbic system is known to play a central role in coordinating social–emotional functioning. An fMRI study of autism has documented dysfunction localized to the ventral temporal lobe using a face recognition task (Baron-Cohen et al., 1999). In this study,

BOX 43.2

DYSLEXIA

Reading skills occupy a uniquely important position in overall cognitive development, strongly dependent on antecedent skill acquisition and critically supportive of educational success. After accounting for the effects of inadequate instruction, the most common cause of severe reading problems in childhood is *developmental dyslexia*, a disorder typically characterized by impairment in applying the sound–correspondence rules necessary to decode print (see Chapter 49). Although reading impairment is common, with an incidence of 5 to 10% among schoolage children, our understanding of its biological roots is relatively recent.

Neurobiological studies of dyslexia are challenging, as the behavioral manifestations of this disorder are complex. Although defined by poor reading performance, dyslexia involves additional deficits, including poor phonological processing, poor verbal working memory, and slow naming ability. Dyslexics frequently show subtle deficits in motor control and early sensory processing, most notably in the visual system. Imaging studies have revealed that dyslexic brain structure differs from that seen in individuals with normal reading skills. Micro and macroscopic structural abnormalities have been detected in perisylvian language regions (temporal and parietal banks of the sylvian fissure as well as the insula), visual system structures, the thalamus, and the corpus callosum. The planum temporale is an expanse of neocortex on the temporal bank of the sylvian fissure, its anterior border defined by Heschl's gyrus. From the time of birth the left planum temporale is larger than the homologous region in the right hemisphere in 70 to 80% of individuals. Reduction or reversal of this leftward asymmetry has been documented in individuals with developmental dyslexia. The functional concomitants of these anatomical variations have been explored in functional imaging studies that have revealed differences in patterns of task-related activity between dyslexics and controls during the performance of reading and phonological decoding tasks. Interestingly, the cortical areas identified are similar in English, French, and Italian dyslexics, supporting a biological origin for this reading abnormality, independent of cultural upbringing. Similarly, candidate genes for dyslexia have been identified and replicated in different countries, suggesting the multigenetic contribution to reading disability.

Besides the problems related to reading, dyslexics also exhibit subtle abnormalities in visual processing. Evidence for selective involvement of magnocellular pathways of the visual system (see Chapter 26) has accumulated, beginning with the demonstration that cell bodies in the magnocellular layers of the lateral geniculate nucleus are smaller in dyslexics compared to a control group. The fact that both contrast sensitivity and visual persistence are abnormal in reading disabled children is consistent with the notion that these children have disturbances in the magnocellular system, which is specialized for temporally demanding visual processing. These behavioral results are supported by functional imaging studies demonstrating less task-related activity in extrastriate and parietal cortex during visual motion detection by dyslexics.

Future studies will determine the nature of the neural mechanisms that link deficits in early visual processing with more cognitive skills such as phonological awareness. Also remaining to be clarified are issues concerning which of these deficits is a primary cause of dyslexia as opposed to a consequence of having partially compensated for a reading disorder. Such information will aid in identifying better avenues for reading remediation. To date, the best methods for improving the reading abilities of dyslexics focus on structured teaching of the code that allows individuals to sound out words (phonological awareness) in the context of fluency and comprehension exercises.

Guinevere F. Eden

high-functioning individuals with autism and matched controls were presented with a series of photographs of eyes while their brains were being scanned to assess brain regions activated by two different tasks. In the first task (experimental condition), each photograph was presented simultaneously with words (either unconcerned or concerned, or sympathetic or unsympathetic). Participants were asked to indicate by pressing a button which word best describes what the person in the photograph is feeling or thinking. In the second task (control condition), each photograph was presented with the words "male" or "female" and the subjects pressed a button to indicate gender. In both tasks, the performance of autistic individuals and controls was above chance. However, the controls were more accurate in the two tasks than the autistic individuals. To investigate the brain regions activated by the experimental task, brain maps obtained during the control task were subtracted from brain maps obtained during the experimental task. In the control group, the experimental task activated two main regions of the brain: the frontotemporal neocortical areas, including the left dorsolateral prefrontal cortex and supplementary motor areas, bilateral temporoparietal regions, and subcortical structures, including the left amygdala and parahippocampal gyrus.

The autism group activated the frontal components but did not activate the amygdala. The significance of these data is that one critical role of the amygdala is to identify the mental states or emotions of other individuals and that this structure appears to be dysfunctional in persons with autism (see Pelphrey and Carter (2008), for additional information on the neuroanatomical substrates of social cognition dysfunction in autism).

Significant atrophy of the vermal lobules in the cerebellum has also been reported in autistic individuals, although this effect does not appear specific to autism and is found widely in neurodevelopmental disorders. By comparison, there is now extensive evidence for the involvement of higher association areas in the pathophysiology of autism, particularly the frontal and parietal cortices, as well as significant remodeling of cortical interconnectivity (Raznahan, Toro et al., 2010). Cytoarchitectural abnormalities that have been described in the cortex of patients with autism include a thickened cortex, high neuronal density, minicolumn alterations, the presence of neurons in the molecular layer, irregular laminar patterns, and poor gray-white matter boundaries.

Autism Is a Complex Genetic Disorder

The most compelling evidence for a genetic contribution to autism comes from studies of monozygotic (identical) and dizygotic (fraternal) twins. When one member of a pair of monozygotic twins is autistic, the other twin has more than a 50% probability of being autistic. However, if one member of a pair of dizygotic twins is autistic, the other twin has only a 3% probability of developing autism. Using conventional nomenclature, we say that monozygotic twins have a 50% or higher concordance for autism and that dizygotic twins have a 3% concordance. The relative risk factor for siblings is one of the highest for a complex genetic disorder. The most significant genetic finding relevant to autism is the recent identification of genes responsible for Rett's syndrome and fragile X syndrome, two conditions associated with autistic features. Rett's syndrome is caused by mutations in the methyl-CpG binding protein 2 (MECP2) gene. Decreased expression of this gene leads to a failure to suppress expression of genes regulated by methylation. Fragile X syndrome is a disorder caused by mutation of the gene FMR1 (see Box 43.3). A better understanding of how reduced expression of the MECP2 and FMR1 genes leads to mental retardation as well as social and language disorders will likely provide a better understanding of the autistic disorder. Over the last several decades, a growing list of rare mutations, such as *NGLN4X, SHANK 3, NRXN1,* have been described in individuals with autism (State, 2010). However, few of these genes are specific to autism and they instead variably contribute to genetic risk for a variety of neuropsychiatric disorders, including schizophrenia and attention-deficit

BOX 43.3

TRIPLET REPEAT DISORDERS

Not all neurogenetic diseases follow simple inheritance patterns; not all developmental disorders reveal themselves immediately; and diseases with similar genetic etiologies can have widely different manifestations. *Trinucleotide repeat mutations*, or *dynamic mutations*, were discovered only in the early 1990s but are responsible for a number of important neurodegenerative disorders, such as Huntington Disease (see Box 31.4), Fragile X mental retardation, and myotonic dystrophy. To date, 14 neurological disorders have been found to result from such a mutational mechanism, and the list will probably continue to grow.

Triplet repeat mutations are unstable and prone to expand as alleles are passed from one generation to the next, although contractions can occur. Repeats at different loci differ markedly in their rates and extents of expansion, and the instability of repeats at each locus often depends upon the sex of the transmitting parent.

Fragile X syndrome, an X-linked dominant mental retardation syndrome, was the first disease shown to result from a triplet repeat mutation. There is a CGG repeat expansion at a locus (Xq27.3) giving rise to a folate-sensitive fragile site (FRAXA). The CGG repeat ranges in length in the general population from 5 to 50 triplets. Affected individuals carry more than 230 repeats, up to several thousand triplets. CGG tracts between 45 and 200 repeats in length are termed "premutations"; they are not long enough to result in mental retardation, yet are prerequisite for further expansion to the full mutation. Escalating risk of affected offspring is associated with increasing size of premutations in female carriers. Curiously, offspring of male carriers of premutations are not at risk for Fragile X syndrome, as these alleles have not been observed to expand to full mutations upon male transmission. The normal function of the affected protein FMR1 remains to be fully determined, but it appears to play a role in RNA metabolism, likely in the areas of transport, stability, and/or translation.

Myotonic dystrophy (DM) remains a particularly enigmatic triplet repeat disorder affecting multiple systems, causing myotonia, muscle weakness, cardiac conduction defects, diabetes, cataracts, premature balding, and sometimes dysmorphic features and mild mental retardation. There is a tendency for these features to appear in more

BOX 43.3 (*cont'd*)

severe form in subsequent generations of a family. In DM there is a CTG repeat in the 3′ untranslated region of the myotonin protein kinase gene (DMPK). This CTG tract is small in the general population (5–37 triplets) but can expand dramatically to thousands of repeats. Slightly increased lengths (70–100) can result in mild effects, such as late-onset cataracts, and the classic symptoms of early adulthood myotonia are found in individuals with hundreds of repeats. Very large expansions can cause severe disease in newborns.

The mechanism(s) by which the mutation leads to the various clinical symptoms remains uncertain. A variety of effects have been described and the repeat expansions clearly affect both the DMPK gene and nearby genes. It is also likely that the expanded CTG repeat carrying mRNAs can act to diminish the levels of nuclear proteins that bind at these sequences, resulting in misregulation of genes not linked to DMPK. Mutations in equivalent mouse genes have not provided a complete model of the human disease. The phenotype in DM results from multiple effects of the repeat expansion, rather than a simple loss or gain of function mechanism.

Friedreich's ataxia (FA) causes both limb and gait ataxia, loss of position and vibration sense, decreased tendon reflexes, cardiomyopathy, diabetes, and, in some patients, optic atrophy and deafness. FA is a recessive disorder and the only triplet repeat disorder known to involve a GAA sequence. Carriers of FA are rather common (1/85), and, consequently, so is the GAA expansion. Members of the general population carry between 7 and 34 repeats, while pathogenic alleles can number in the hundreds. The affected frataxin gene product appears to be involved in mitochondrial iron homeostasis, and its absence affects postmitotic cells rich in mitochondria. The mechanism by which the GAA repeat affects gene function appears to be inhibition of primary RNA transcripts.

A second class of triplet repeat disorders includes those caused by expansion of translated CAG repeats which encode a polyglutamine tract in each of the respective proteins. These "polyglutamine" disorders share many features, suggesting that a common pathogenetic mechanism is at play in spite of the fact that the mutated genes share no homology outside of the CAG repeats. They are progressive neurologic diseases with onset of symptoms in young to midadulthood with only a specific group of neurons vulnerable in each disease. Symptoms develop when the number of uninterrupted repeats exceeds approximately 35 glutamines. The phenotype is caused not by loss of function of the relevant protein but rather by a gain of function conferred by the expanded polyglutamine tract.

The *spinocerebellar ataxias (SCA)* are genetically distinct but overlap a great deal in their clinical presentation—between subtypes and even within families affected by the same disease. It is nearly impossible to distinguish one subtype from another on the basis of clinical signs alone. *Spinocerebellar Ataxia Type 1 (SCA1)* was the first of the inherited ataxias to be mapped. Patients with SCA1 suffer from progressive ataxia (loss of balance and coordination), dysarthria, and eventual respiratory failure. SCA1 is characterized pathologically by cerebellar atrophy with severe loss of Purkinje cells and brain stem neurons. Patients with SCA1 have an expanded "perfect" CAG repeat tract encoding ataxin-1, the function of which is largely unknown.

Studies of human patients with deletions of, for example, the HD, or SCA1 genes (and of mice lacking these genes) confirm that disease is not due to loss of function of the respective proteins. More importantly, studies of mouse and fruit fly models that over-express full-length or truncated forms of either ataxin-1, ataxin-3, huntingtin, AR, atrophin-1, or ataxin-7 demonstrate progressive neuronal dysfunction consistent with a gain of function mechanism. Several illuminating findings have emerged from the study of human patients, cell culture systems, and the various animal models. In transgenic mice, expression of truncated polypeptides containing expanded glutamine tracts caused widespread dysfunction that extends beyond the specific groups of neurons affected by the full-length protein. The expanded polyglutamine tracts may cause the respective proteins to misfold or resist degradation. Aberrant protein-protein interactions or alterations in levels of proteins essential for the normal functioning of neurons (such as proteins that regulate Ca^{+2} levels and neurotransmitters) could, in turn, exacerbate neuronal dysfunction and lead to neuronal death.

The finding that chaperone overexpression mitigates the phenotype in one vertebrate and several invertebrate models of polyglutamine disorders, and the identification of several additional modifiers of the neuronal phenotype, provide a platform for identifying key pathways of pathogenesis and potential therapeutic targets.

hyperactivity disorder (ADHD). Although the findings provide tremendous promise, they also highlight the many challenges facing the study of the genetics of autism.

Schizophrenia

Schizophrenia is a catastrophic illness with an onset typically in adolescence or early adulthood. It was identified and defined by Eugen Bleuler in 1911. The combination of significant incapacity, onset early in life, and chronicity of illness makes schizophrenia a particularly tragic disorder, occurring in 0.5 to 1% of the population.

Characteristics of Schizophrenia

The clinical symptoms of schizophrenia are often divided into two broad categories: positive and negative. Positive symptoms include delusions, hallucinations, disorganized speech, and disorganized or bizarre behavior. These symptoms are referred to as positive because they represent distortions or exaggerations of normal cognitive or emotional functions. The negative symptoms of schizophrenia reflect a loss or diminution of normal function. Negative symptoms include alogia (marked poverty of speech or speech devoid of coherent content), affective flattening (diminution in the ability to express emotion), anhedonia (inability to experience pleasure); avolition (inability to initiate or persist in goal-directed behavior), and attentional impairment. Although the positive symptoms of schizophrenia are often colorful and draw attention to the patient's illness, the negative symptoms are an important feature of the disease that impair the person's ability to function normally in daily life.

The profound and pervasive cognitive and emotional disturbances that characterize schizophrenia suggest that it is a serious brain disease affecting multiple functions and systems. Auditory hallucinations and disruptions in linguistic expression suggest involvement of the auditory cortex and perisylvian language regions. Other positive symptoms, such as delusions or disorganized behavior, are more difficult to localize to specific regions and suggest dysfunction distributed across multiple neural systems and circuits. Negative symptoms may be related to the prefrontal cortex, which mediates goal-directed behavior and fluency of thought and speech. The affective flattening and asociality suggest involvement of the limbic areas within the temporal lobe.

The Dopamine Hypothesis of Schizophrenia

A great deal of research since the 1950s has made it clear that schizophrenia is associated with abnormalities in the dopaminergic synapses of the brain. Still, the exact nature of this perturbation remains elusive. The strongest link between dopamine synapses and schizophrenia comes from studies of drugs that alleviate the symptoms of schizophrenia. A large number of antischizophrenic, or neuroleptic, drugs have been found, most of which belong to two chemical families, the phenothiazines, which include chlorpromazine, and the butyropherones, which include haloperidol. All of these drugs have two properties in common: they block postsynaptic dopamine receptors and they inhibit the release of dopamine from the presynaptic neuron. One interpretation of these results is that schizophrenia is due to excess activity at dopamine synapses. Establishing cause-and-effect relationships in human psychiatric disorders, however, is challenging. For example, although a substantial increase in the number of dopaminergic receptors is observed in the schizophrenic brain, because virtually all patients receive neuroleptic medication, it is not known if increased receptor density is a consequence of the disease itself or a response to the extended use of antidopaminergic drugs. An additional complication for the dopamine receptor hypothesis of schizophrenia concerns the time course for the effects of neuroleptic drugs. Although these treatments block dopamine receptors almost at once and reach their full pharmacological effectiveness within a few days, effects on behavior emerge more slowly, over 2 or 3 weeks. Clearly the symptomatic relief achieved with neuroleptic intervention involves mechanisms in addition to the blockade of dopamine receptors.

One possibility is that the prolonged use of neuroleptic drugs decreases the number of spontaneously active dopamine neurons in what is known as the mesolimbic system, a set of neurons that projects from the midbrain tegmentum to the limbic system. Another possibility is that the underlying problem in schizophrenia is not an excess of dopamine activity at all, but a deficit of glutamate activity. Glutamate is the predominant excitatory amino acid released by neurons in the cerebral cortex that project widely throughout the limbic system, and dopamine synapses are known to inhibit glutamate release in these target regions. If glutamate release is reduced in the schizophrenic brain, one way to correct this deficiency would be to block activity at dopaminergic receptors, relieving glutamate synapses from inhibition.

Neuropathological Alterations in Schizophrenia

The most consistently described structural alterations in schizophrenia are ventricular enlargement and decreases in the volume of temporal lobe structures, including the hippocampus, amygdala, and entorhinal cortex. Cytoarchitecture and cell densities are also reportedly altered in limbic structures: reduced cell number and size have been observed in the hippocampus, parahippocampal gyrus, and entorhinal cortex, along with disturbed cytoarchitecture involving cellular disarray in the hippocampus and the entorhinal and cingulate cortices. This distribution of structural abnormalities may help account for the symptoms of schizophrenia in that these limbic structures

link neocortical association areas with the septum–hypothalamic complex and are therefore key in sensory information processing and sensory gating. Defects in this neural circuit could lead to a dissociation between neocortically mediated cognitive processing and limbic–hypothalamic emotional reactions and to a disturbed emotional experience of external sensory perceptions.

The structural alterations reported in schizophrenia are often subtle and certainly heterogeneous, contributing minimally to the elucidation of the disease if symptoms are to be attributed to defects in individual brain regions. Alternatively, it is currently hypothesized that the variety and severity of symptoms observed in schizophrenia can be explained by defects in several brain regions affecting the neural circuits that mediate higher cognitive functions. Such neural circuitry would include neocortical association areas, the limbic system and midline thalamic structures, with possible involvement of the basal ganglia.

The Neurodevelopmental Hypothesis of Schizophrenia

Several clinical observations point to neurodevelopmental abnormalities in schizophrenia: onset in adolescence in most patients and earlier onset among males, pronounced premorbid neurodevelopmental abnormalities, such as asociality and "soft" neurological signs, impaired cognitive and neuromotor functioning, minor physical anomalies, presence of structural abnormalities at the onset of the illness, which may predate the illness, and the absence of neurodegenerative processes.

Postmortem morphological observations in the brains of schizophrenic patients suggest that multiple aspects of neural development may be disrupted. The spatial disorganization of neurons found in the hippocampus and the inappropriate laminar location of cells in the entorhinal cortex, for example, suggest a potential defect in neuronal migration. Other evidence indicates that the organization of synaptic connectivity is affected. The functional circuitry of the frontal cortex undergoes significant remodeling until adolescence, mediated by an NMDA receptor-dependent mechanism. The number of these receptors is reduced in the brain of schizophrenics. Still other abnormalities involve biochemical alterations of membrane phospholipids in the dorsolateral prefrontal region. These changes include a decrease in phosphomonoesters and an increase in phosphodiesters. Such biochemical changes in membrane phospholipids are known to occur during normal synaptic pruning in adolescence, but appear to be exaggerated in the dorsolateral prefrontal cortex of schizophrenics. These enhanced biochemical changes may lead to greater synaptic pruning in schizophrenics than in normal individuals and contribute to the reduction in prefrontal neuropil volume that accompanies the disease.

The precise timing of neurodevelopmental abnormalities in schizophrenia remains controversial. Some implicate a fixed neural lesion from early life interacting with normal neurodevelopmental events that take place much later. Others posit that schizophrenia is caused by a deviation from normal brain maturational processes during late adolescence, involving large-scale synaptic elimination or pruning in brain regions critical for cognitive development. Still others propose that early brain pathology acts as a risk factor rather than a sufficient cause so that its effects can only be understood in the light of the individual's later exposure to other risk and protective factors.

Genetics Play a Role in Schizophrenia

As for autism, a substantial body of evidence indicates that schizophrenia is associated with both genetic and environmental factors. Findings pointing to a significant genetic contribution come from family, twin, and adoption studies. Evidence for environmental factors derives from studies of prenatal intrauterine environment, neonatal obstetric complications, and postnatal brain insults. Currently, it remains an open question whether these environmental factors play a necessary role in the neurodevelopmental abnormalities responsible for psychotic brain disorders or whether their role is additive or interactive with genetic contributions.

People with schizophrenia are more likely than others to have schizophrenic relatives. The most compelling evidence is the 50% concordance rate for monozygotic twins relative to 15% concordance for dizygotic twins. Neuroimaging studies of discordant monozygotic twins consistently indicate more prominent structural brain abnormalities in the ill twin. More importantly, a neuroimaging study demonstrated that schizophrenia is associated with dysfunction of a prefrontal-limbic network (Weinberger, Berman, Suddath, & Torrey, 1992). In this study, monozygotic twins discordant for schizophrenia underwent PET blood flow scans while they performed a task known to activate the dorsolateral prefrontal cortex in normal subjects. This assessment, known as the Wisconsin Card Sorting Task (WCST), measures abstract problem solving requiring attention and working memory (see Fig. 50.4). The participant sees four cards bearing designs that differ in color, form, and number of elements. The subject's task is to sort the stack of cards into piles in front of the stimulus cards. The subject is told whether the sorting choice is correct or incorrect. The test progresses such that the correct solution is initially stimulus color. Once mastered, the correct sorting strategy is switched without warning to form, requiring subjects to inhibit classifying cards on the basis of color. In a final phase the correct solution again changes unexpectedly, now to the number of elements. Shifting response strategies is difficult for patients with frontal lobe dysfunction. Among affected

schizophrenic twins, prefrontal activation correlates strongly with both left and right hippocampal volumes; a relationship that is not observed in their unaffected twins. In addition, functional connectivity between the hippocampus and prefrontal cortex as measured by fMRI is weaker in schizophrenic patients than controls. These data suggest that schizophrenia may result from dysfunction distributed across a neural network involving prefrontal cortical areas and limbic structures.

Molecular studies demonstrate that schizophrenia is a complex genetic disorder, implicating several possible susceptibility loci, including regions on chromosomes 1q, 6p, 8p, 13q, and 22q. Of genes mapped, the 22q11 gene [a common functional polymorphism of catechol-*O*-methyltransferase (COMT), which is a methylation enzyme that metabolizes released dopamine] has been a popular candidate because of the long-hypothesized role of dopamine in schizophrenia. Recent molecular imaging studies in humans have also established that schizophrenia is associated with alterations in the dopamine system and these neurotransmitter abnormalities are shared by individuals at genetic and clinical risk for developing the illness.

Sex Hormones May Influence Neurodevelopmental Disorders

There are gender differences in the occurrence of neurodevelopmental disorders. The gender ratio of incidence is skewed toward boys for a variety of developmental disabilities, including severe mental retardation (1.3 boys/1 girl), speech and language disorders (2.6/1), learning difficulties (2.2/1), dyslexia (4.3/1), schizophrenia (1.9/1), and autism (4/1). Why? Although the existence of sex differences in the area of language and learning disorders has been contested on the grounds that it is a result of teacher and clinician bias in identifying these disorders, research supports the existence of a significant gender difference in the incidence of these disorders. Moreover, gender differences are also seen in clear-cut phenomena such as complications of pregnancy and birth, which are more common in male infants, and these differences cannot be explained as a reflection of investigator or clinician bias. Several theories attempt to explain these gender differences.

One theory posits that male but not female fetuses invoke a form of "antigenic" response from the mother during pregnancy, being recognized by the immune system as "foreign." The hostile environment thus created for the male fetus *in utero* would explain not only a higher incidence of developmental disorders among boys, but also the finding that later-born sons are increasingly likely to be affected (consistent with increased immune responsiveness on repeated exposure).

Another theory (termed the Geschwind theory, after the neurologist Norman Geschwind) proposed that the uneven gender ratios in developmental disorders are associated with exposure to some "male factor" (possibly androgen) during the last trimester of fetal development. This factor acts to slow cortical maturation in male fetuses, particularly in the left hemisphere, rendering them more susceptible to perturbation during the normal course of development. This exposure to a male hormone would explain the higher incidence of developmental disorders among boys. Conversely, faster central neurons system development in female fetuses would enable them to better withstand insult during late pregnancy and birth. This idea is supported by evidence that female infants appear to show better cognitive recovery than male infants from intracranial hemorrhage associated with prematurity.

Summary

This section examined two forms of developmental abnormalities: autism and schizophrenia. In both cases it is possible to link the behavioral manifestations of the disorder to anomalies in neurobiological systems and to identify a genetic component. In both disorders, too, affected individuals do not show localized damage in circumscribed brain regions, but show evidence of cellular disturbance early in brain development (i.e., during neuromigration), which gives rise to pervasive and dysfunctional reorganization of critical neural systems underlying complex behaviors. Emerging evidence suggests that similar mechanisms may characterize other developmental disabilities, including dyslexia, mental retardation, and attention deficit disorders. Current findings also support the existence of sex differences in brain development and organization, which may in turn differentially affect the response of the brain to early injury.

PATHOLOGICAL MANIFESTATIONS OF COGNITIVE AGING: DEMENTIA

Dementia is a generic term that refers to debilitating deterioration in more than one domain of cognitive function. The involvement of multiple capacities distinguishes dementia from other disorders, such as amnesia and aphasia, that affect a single functional domain (memory and language, respectively). Approximately 50 disorders are known to cause dementia. Most of these are progressive in nature, increasing in severity over time. The age at onset and the rate of progression of symptoms differ dramatically among the major dementing disorders. Most have an insidious onset and develop slowly, sometimes over a period of many years. These include Alzheimer's disease, Huntington's disease, frontotemporal dementia, and the dementia observed in a subpopulation of patients with

Parkinson's disease. The rare neurodegenerative disorder Creutzfeldt–Jakob disease also develops insidiously, but is distinguished by a very rapid rate of progression, often spanning a year or less from the onset of dementia to death. Vascular dementia (or multi-infarct dementia) follows still another pattern of decline. Initial cognitive symptoms develop acutely, but in this case the clinical course typically proceeds in a step-wise fashion over many years, with periods of relative stability punctuated by abrupt deterioration. Age is a major risk factor for dementing illnesses, and the following sections focus on the most prevalent example; Alzheimer's disease.

Alzheimer's Disease Is the Most Common Cause of Dementia

In 1906, the German scientist Alois Alzheimer reported a case study of a woman in her late 40s who developed memory impairment and deficits in other mental faculties that progressively worsened in severity until her death in her early 50s. Subsequent neuropathological examination of this patient's brain revealed grossly apparent and widespread neocortical atrophy that Alzheimer concluded was inconsistent with any previously described disease. Although the disorder that would come to bear his name was originally thought to be quite rare, Alzheimer's disease is now recognized as the most common cause of dementia, accounting for an estimated 50% of all cases, and the fifth leading cause of death among those over 65 years of age. Current estimates are that more than 5 million people in the United States, and 26 million people worldwide, suffer from Alzheimer's disease. The prevalence of the disease is tightly coupled to age and increases after the fourth decade of life. The disease affects about 12% of people over the age of 65, and by 85, as many as 40% are afflicted. Demographic trends indicate that the elderly comprise the fastest growing segment of the population, and as a consequence, the number of people suffering the devastating impact of Alzheimer's disease is projected to nearly triple by 2050. Not surprisingly, efforts to understand the basis of this and related disorders are among the most active research areas in neuroscience.

Memory Impairment Is a Central Feature of Alzheimer's Disease

Alzheimer's original case study provided an accurate description of the clinical course for many patients with this disease. Impairment in establishing and maintaining memories for recent events is frequently the initial sign that brings the patient to the attention of health care professionals. At this early stage, memory for the remote past is relatively preserved, as are other forms of memory that do not require medial temporal lobe structures. Thus, the neuropsychological profile of the Alzheimer's patient provides important clues about the neuropathological progression of this disorder, suggesting that the systems responsible for declarative memory are especially vulnerable. Neuroanatomical studies of the diagnostic hallmarks of Alzheimer's disease (described in the next section) confirm this proposal. Progression of the disorder is marked by inexorable decline across multiple cognitive capacities. Although generally alert and responsive in early and middle phases of the disorder, Alzheimer's patients often experience difficulty identifying the meaning of simple words, uses for common household objects, or the meaning of numbers. Other disturbances can include general confusion, agitation, delusions, social disinhibition, and paranoia. Language abilities can deteriorate progressively, and at the end stage of disease, patients are often mute and densely amnesic for both recent and more remote events. As might be predicted on the basis of this broad profile of impairment, the distribution of neuropathology in individuals dying with late-stage Alzheimer's disease is extensive, involving widespread areas of the limbic system and association cortices, along with many subcortical brain regions, including the basal forebrain cholinergic system, striatum, thalamus, and cerebellum.

Amyloid-Containing Plaques and Neurofibrillary Tangles Are Diagnostic Hallmarks of Alzheimer's Disease That Preferentially Target Memory-Related Brain Regions

There are two types of neuropathological lesions that, when present in sufficiently high numbers, are the diagnostic hallmarks of Alzheimer's disease (Fig. 43.6). Plaques comprise extracellular deposits of amyloid β-protein (Aβ) that, in their mature form, are typically surrounded by a

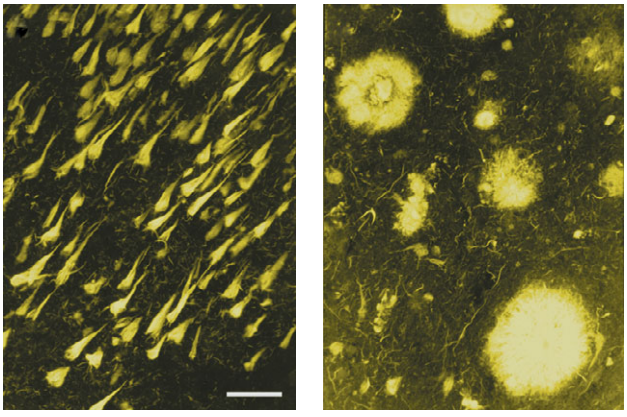

FIGURE 43.6 Photomicrographs of neurofibrillary tangles (A) and amyloid-containing plaques (B) in the hippocampal formation of a patient that died with late-stage Alzheimer's disease. Note that the size and morphological characteristics of plaques in B vary widely. Scale bar: 50 μm. *Courtesy of P. Hof, Mount Sinai School of Medicine.*

shell of dystrophic neurites (see Fig. 43.6B). The neuritic component of plaques consists of morphologically abnormal dendrites and axons of multiple neuronal types, typically associated with substantial numbers of glial cells. The amyloid core of plaques can contain multiple species of Aβ, but prominently includes a form ending at amino acid 42 that is prone to aggregation (Aβ_{42}), and a slightly shorter species (Aβ_{40}) that is normally produced more abundantly in neurons. Plaques vary substantially in size, and although the time it takes for mature neuritic plaques to form is not known precisely, they are likely to evolve slowly, over many years.

In contrast to extracellular plaques, the second neuropathological hallmark of Alzheimer's disease is localized intracellularly. Termed neurofibrillary tangles, these are composed of densely packed, abnormal fibers that occupy much of the cytoplasm and proximal neuronal processes of affected cells (Fig. 43.6A). Indeed the density of these fibers in many tangle-bearing neurons is sufficiently high that the cell body appears swollen and the nucleus displaced. The term "paired helical filaments" (PHF), sometimes used to describe this type of pathology, derives from electron microscopic evidence that tangles consist of pairs of twisted filaments with a highly regular periodicity. Studies using biochemical and immunocytochemical methods have demonstrated that PHF are composed of a cytoskeletal protein found in normal, healthy neurons: the microtuble-associated protein tau. Cytoskeletal abnormalities can disrupt intracellular trafficking of materials that are critical for cell viability, culminating in neuron death. Defining the mechanisms that initiate the hyperphosphorylation of tau and its aggregation into mature neurofibrillary pathology is a prominent avenue of research on Alzheimer's disease.

Investigations aimed at mapping the neuroanatomical distribution of pathology during early and later stages of Alzheimer's disease help account for the progression of clinical symptoms in patients with this disorder. Early in the course of the disease, when memory impairment is often the predominant complaint, plaques and tangles are particularly abundant in the entorhinal cortex and associated projection targets in the hippocampus. Indeed, in many cases virtually all of the neurons that originate the perforant path projection to the hippocampus exhibit neurofibrillary tangles. Emerging evidence also suggests the balance of excitatory and inhibitory drive is disrupted in vulnerable circuitry early in the course of the disease, perhaps contributing to Aβ deposition. In this way the pathophysiology of Alzheimer's disease appears to initially target cortical networks critical for normal memory. As the severity of cognitive impairment progresses, the distribution of neuropathology becomes more widespread, affecting cortical and subcortical systems that support language, semantic knowledge, abstract reasoning, and other capacities.

Genetic Contributions to Alzheimer's Disease

Important clues about the basis of Alzheimer's disease have come from the study of people afflicted with an "early onset" form of the disorder that emerges before the age of 65. This relatively rare and aggressive condition exhibits an increased prevalence in certain families and is therefore thought to have a significant genetic component. To date, three gene mutations linked to early onset Alzheimer's have been identified: one involving the amyloid precursor protein gene on chromosome 21, another in the presenilin 1 gene on chromosome 14, and the third in the presenilin 2 gene on chromosome 1. Each of these mutations is expressed in an autosomal-dominant fashion such that half the offspring of an affected parent develop the disease. Importantly, the common thread among the gene mutations that cause early onset Alzheimer's disease is that each of them influences processing of the amyloid precursor protein (reviewed in Selkoe, 2001).

Several additional lines of evidence support the suggestion that the deposition of amyloid is central to the pathogensis of Alzheimer's disease. By far the most common form of the disorder (accounting for an estimated 98% of cases) has a relatively late onset, after age 65. Among a number of recently identified candidate genes, one risk factor for late-onset Alzheimer's disease is the allelic composition of the apolipoprotein E gene on chromosome 19 (ApoE)—that is, a gene that codes for a glycoprotein involved in cholesterol transport and metabolism. The ApoE gene has three alleles (designated ApoE2, ApoE3, and ApoE4), and patients with Alzheimer's disease carry the ApoE4 allele with a frequency greatly exceeding individuals without the disease. Moreover, the risk of disease is coupled to the number of copies of this specific allele: individuals with no copies of ApoE4 are less likely than the general population to develop Alzheimer's disease, the presence of one ApoE4 allele increases the disease risk four times, and people with two copies of ApoE4 are eight times more likely than the population at large to develop Alzheimer's. Although the precise mechanism by which ApoE4 mediates disease susceptibility is unknown, one hypothesis is that it involves the disruption of processes responsible for scavenging and clearing amyloid peptide from the extracelluar space in brain.

Additional findings relevant to the role of amyloid in Alzheimer's disease come from research on Down's syndrome. Down's syndrome results from the presence of an extra copy of the same chromosome that carries the gene for the amyloid precursor protein; chromosome 21. Thus, it is of considerable interest that people with Down's syndrome who survive until the fourth decade of life

invariably develop a distribution of amyloid plaques in the brain similar to Alzheimer's patients. To the degree that aberrant processing or clearance of amyloid comprises the common pathogenic mechanism of Alzheimer's disease, current findings encourage the view that interventions targeting this pathway might realize an effective treatment for the most common cause of age-related dementia.

Prospects for the Treatment of Alzheimer's Disease

Although Alzheimer's disease is presently incurable, several pharmacological treatments have been approved for the clinical management of cognitive impairment associated with the disorder. All of these treatments target either acetylcholine or glutamate signaling, and while they offer modest, transient benefit for some Alzheimer's patients, they fall far short of an effective cure or prevention. Preclinical progress toward the latter goal includes evidence that immunization with Aβ can both attenuate spatial learning impairment and blunt the progression of amyloid deposition in transgenic mouse models of Alzheimer's disease (reviewed in Selkoe, 2001). Translating this approach to clinical practice faces substantial challenges, and initial attempts indicate that parallel treatment in people can induce life threatening cerebral inflammation. Nonetheless, the recent development of techniques for imaging brain amyloid deposition in vivo has generated considerable excitement, suggesting that it may soon be possible to identify at risk individuals very early in the course of disease, prior to the onset of cognitive decline, when intervention is most likely to be beneficial. The hopeful outlook based on these findings is that vaccine therapies might ultimately yield an effective route for the treatment and prevention of Alzheimer's disease.

Summary

This chapter has considered the neurobiology of cognitive development and aging. Early cognitive development is marked by the emergence of a remarkably complex set of adaptive capacities, including language skills, reasoning abilities, attention, declarative memory, and executive functions. The vast majority of neurons—the essential building blocks of the central nervous system—are present at birth in humans, and rather than depending on the recruitment of new neurons, cognitive development appears to involve the fine tuning and establishment of appropriate circuitry among existing cells. Given the complexity of orchestration required, it is not surprising that many major disorders affecting cognitive function appear to result from a disruption of normal neurodevelopmental events. Higher order cognitive capacities are also vulnerable to deterioration during normal aging. Whereas widely distributed neuron death was previously presumed to underlie these deficits, it now appears that regionally selective changes in connectivity and cell biological function in critical circuits are the causative factors. Aging is also associated with some of the most devastating pathological conditions affecting cognitive function, including Alzheimer's disease. The dramatic progress realized in recent years has, for the first time, established a basis for the rational development of strategies for disease prevention and treatment.

Visual Perception of Objects

THE PROBLEM OF OBJECT RECOGNITION

Accurate perception and recognition of objects is a crucial ability for visually dependent organisms such as humans—but it is also a complex one. As object and viewer move with respect to each other, the images cast by the object on the retinas of the observer can change radically. Not only will image position and size change, but surfaces may be foreshortened, occluded, or newly revealed. Similarly, changes in ambient illumination can reveal new surfaces, hide others in shadow, or introduce spurious edges where light ends and shadow begins. Despite this, human and nonhuman primates recognize objects quite readily. This means that the visual system is able to extract a reasonably constant "representation" for the shapes and identities of meaningful objects despite such transformations. Image processing by the retina, visual thalamus, and primary visual cortex begins this process by extracting features and representing them over progressively larger receptive fields. However, in order to understand how the brain represents the identity of an object—its defining, invariant features of shape, relations among parts, and its significance—one must examine how circuits beyond the primary visual cortex encode and retain crucial information of a more global or "high-level" nature.

Visual processing can be subdivided into low-level, intermediate-level, and high-level components. The initial, low-level stages are those in which the brain extracts information about the physical properties of the stimulus, such as the edges, brightness, color, and motion of objects present in scenes (see Chapter 26). This processing often is described as bottom-up because it can proceed from low (input) levels up through the visual system without feedback from cognitive processes such as memory. Intermediate-level vision involves combining information about these physical properties in order to detect global properties of an object, such as object shape and the orientation of the object in depth. High-level processes include those that endow the stimulus with meaning, leading to object recognition and classification. For example, recognition and classification depend on object knowledge and context, and can therefore be considered top-down because the neural processing is influenced directly and profoundly by cognitive factors. Other top-down mechanisms, such as selective attention, can operate at even early stages of visual processing (see Chapter 46).

This chapter is concerned primarily with the neural basis of the high-level components of object vision. First, historical evidence is reviewed that helped localize the crucial circuitry to the ventral parts of the temporal cortex. Next, from studies in nonhuman primates, the main pathways are described for object perception and recognition. The complex features of temporal cortex neurons involved in object perception are outlined. Neuroimaging and electrophysiological studies are reviewed to show that very similar processing pathways and mechanisms exist in humans. In addition, human studies are reviewed to consider how the brain may treat special categories of objects and the ways in which experience with objects tunes their neural representations. Finally, visual object perception is considered in the broader context of general object knowledge and memory.

SUBSTRATES FOR OBJECT PERCEPTION AND RECOGNITION: EARLY EVIDENCE FROM BRAIN DAMAGE

Early Studies of Human Patients Pointed to the Inferior Temporal Cortex as a Site for Object Agnosia

During the late nineteenth century, researchers were occupied with locating the visual centers of the brain. In 1881, Hermann Munk reported that while lesions to occipital cortex produced a complete loss of vision, lesions to temporal cortex resulted in something quite different. He found that temporal lobe lesions in monkeys and dogs would cause the animals to ignore food and water, even if hungry and thirsty. However, they could still navigate rooms and avoid obstacles placed in front of them, indicating that their visual acuity was, at least partially, intact (Brown & Schafer, 1888; Munk, 1881). Munk referred to this syndrome as "psychic blindness," now referred to as visual agnosia, to describe the apparent inability of the animal to understand the meaning of the visual stimuli presented.

Visual agnosia has since been demonstrated in humans who have suffered damage to the occipital and temporal cortices. It refers to a set of disorders affecting object recognition, in which elementary visual capacities such as acuity and visual fields are preserved or grossly intact (for review, see Farah, 2004). Writers such as Potzl in 1928 noted the importance of inferior regions of the temporal lobes, along with adjacent ventral occipital cortex, in most cases of visual agnosia. Subsequent studies upheld these general findings and confirmed the central role of the lingual and fusiform gyri (Fig. 44.1). Patients with visual agnosia typically have bilateral (or, less commonly, right-sided) damage to these regions.

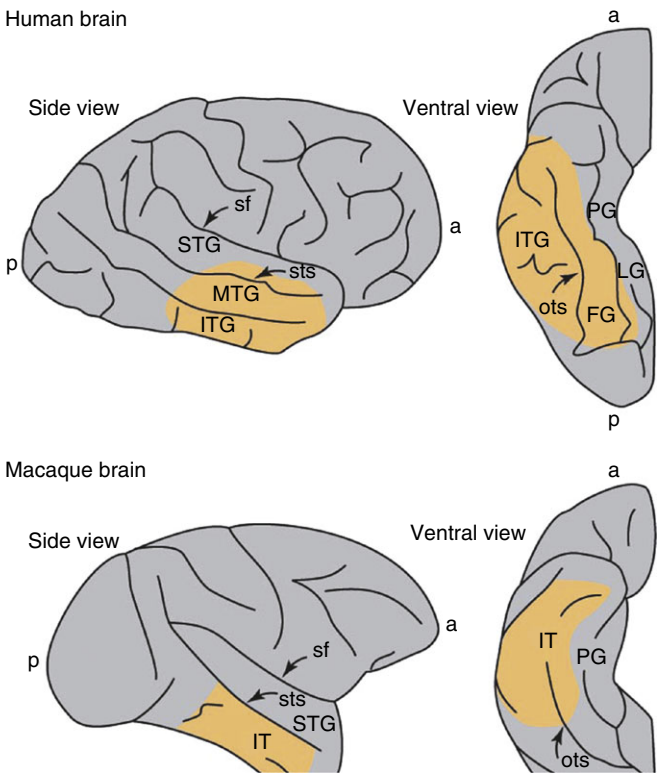

FIGURE 44.1 (Top) Region of the human brain (in shading) within which large bilateral or right-sided lesions cause associative visual agnosia. (Bottom) Region in the macaque monkey (in shading) referred to as the inferior temporal cortex, within which bilateral lesions cause visual discrimination and recognition deficits analogous to agnosic syndromes in humans. a, anterior; p, posterior. FG, fusiform gyrus; ITG, inferior temporal gyrus; LG, lingual gyrus; MTG, middle temporal gyrus; PG, parahippocampal gyrus; STG, superior temporal; ots, occipito-temporal sulcus; sf, Sylvian or lateral fissure; sts, superior temporal sulcus.

Two Types of Visual Agnosia Have Been Distinguished Historically

Two forms of visual agnosia have been characterized. Agnosic patients, whose elementary perception of shape is impaired (despite intact or roughly normal visual acuity) are classified as *apperceptive agnosics* because their impairment is presumed to be at an early stage of the perceptual processing needed for object recognition. Patients suffering from apperceptive agnosia have difficulty with simple discrimination tasks, copying pictures, and cannot name or categorize objects. Patients with such deficits are relatively rare. Usually they have suffered diffuse brain damage, often from carbon monoxide poisoning.

Patients suffering from *associative agnosia* can successfully identify and copy shapes. However, their ability to associate any meaning with the images is severely impaired. Associative agnosia often involves damage to the inferior portions of the posterior cortex, the ventral occipital cortex and/or the lingual and fusiform gyri in the posterior temporal lobe. Associative agnosia is diagnosed according to the following criteria: First, the patient must show difficulty recognizing visually presented objects, as measured by both naming and nonverbal tests of recognition, such as sorting objects by category (e.g., grouping kitchen utensils together, separate from sports equipment) or pantomiming the uses of the object. Second, the patient must show knowledge of the objects through sensory modalities other than vision; that is, be able to recognize items by sound or touch or through verbal questioning ("What is an egg beater?"). Third, the patient must have sensory and perceptual capacity sufficient to allow him or her to describe the appearance of an unrecognized object, to draw it, or identify whether it is the same as or different from a second item. An illustrative case of associative visual agnosia is summarized in Box 44.1. Figure 44.2 shows some copies drawn by this patient, who nevertheless did not recognize the pictures he copied.

BOX 44.1

CASE STUDY OF ASSOCIATIVE AGNOSIA

The subject was a 47-year-old man who had suffered an acute loss of blood pressure with resulting brain damage. His mental status and language abilities were normal, and his visual acuity was 20/30, with a right homonymous hemianopia (blindness in the right visual hemifield). His one severe impairment was an inability to recognize most visual stimuli. For the first three weeks in the hospital, the patient could not identify common objects presented visually and did not know what was on his plate until he tasted it. He identified objects immediately on touching them.

When shown a stethoscope, he described it as "a long cord with a round thing at one end" and asked if it could be a watch. He identified a can opener as a key. Asked to name a cigarette lighter, he said, "I don't know" but named it after the examiner lit it. He said he was "not sure" when shown a toothbrush. He was never able to describe or demonstrate the use of an object if he could not name it. If he misnamed an object, his demonstration of use would correspond to the mistaken identification. Identification improved very slightly when given the category of the object (e.g., something to eat) or when asked to point to named object instead of being required to give the name. When told the correct name of an object, he usually responded with a quick nod and often said, "Yes, I see it now." Then, often he could point out various parts of the previously unrecognized item as readily as a normal subject (e.g., the stem and bowl of a pipe and the laces, sole, and heel of a shoe). However, if asked by the examiner, "Suppose I told you that the last object was not really a pipe, what would you say?" He would reply, "I would take your word for it. Perhaps it's not a pipe." Similar vacillation never occurred with tactilely or aurally identified objects.

After he had spent three weeks on the ward, his object naming ability improved so that he could name many common objects, but this was variable; he might correctly name an object at one time and misname it later. Performance deteriorated severely when the examiner covered any part of the object. He could match identical objects but could not group objects by categories (clothing, food). He could draw the outlines of objects (key, spoon, etc.) that he could not identify.

He was unable to recognize members of his family, the hospital staff, or even his own face in the mirror. Sometimes, he had difficulty distinguishing a line drawing of an animal face from a man's face but always recognized it as a face. The ability to recognize pictures of objects was impaired greatly, and after repeated testing he could name only one or two of 10 line drawings. He was always able to name geometrical forms (circle, square, triangle, cube). Remarkably, he could make excellent copies of line drawings and still fail to name the subject. He easily matched drawings of objects that he could not identity and had no difficulty discriminating between complex nonrepresentational patterns, differing from each other only subtly. He occasionally failed in discriminating because he included imperfections in the paper or in the printers' ink. He could never group drawings of objects by class unless he could first name the subject. Reading, both aloud and for comprehension, was limited greatly. He could read, hesitantly, most printed letters but often misread "K" as "R" and "L" as "T" and vice-versa. He was able to read words slowly by spelling them aloud.

Excerpt from Rubens AB and Benson, D. F. (1971). Associative visual agnosia. Archives of neurology, 24, *305–316.*

Associative Visual Agnosia Involves Deficits in Invariant Object Representations

Closer examination of the manner in which associative agnosics copy and match pictures they cannot identify shows that they are often abnormally attentive to the small details of the image, rather than being guided by the overall shape or "gestalt" of the object itself. This copying is done in a slow, line-by-line fashion, and patients may classify two pictures as different because of a small flaw in the printing. These observations suggest that the associative agnosic patients are unable to match what is in front of them to a unified, stored visual representation of the object. Such stored representations likely include knowledge about the invariant, distinguishing visual attributes (such as the general body shape and relative placement of features of the pig in Fig. 44.2) and/or stored semantic knowledge (the identity of the object as a pig). The underlying problem in visual agnosia could thus result from an inability to generate a high-level representation of the object (a perceptual deficit), a permanent loss of previously stored representations (a memory deficit), or an inability to link the two. In fact, some evidence suggests that different agnosic patients are impaired in distinct stages of visual processing and storage. At the same time, recent work suggests that, at the neural level, "perceptual" and "memory" processes for objects may use the same circuitry (and thus, might be experimentally inseparable), as discussed later in this chapter.

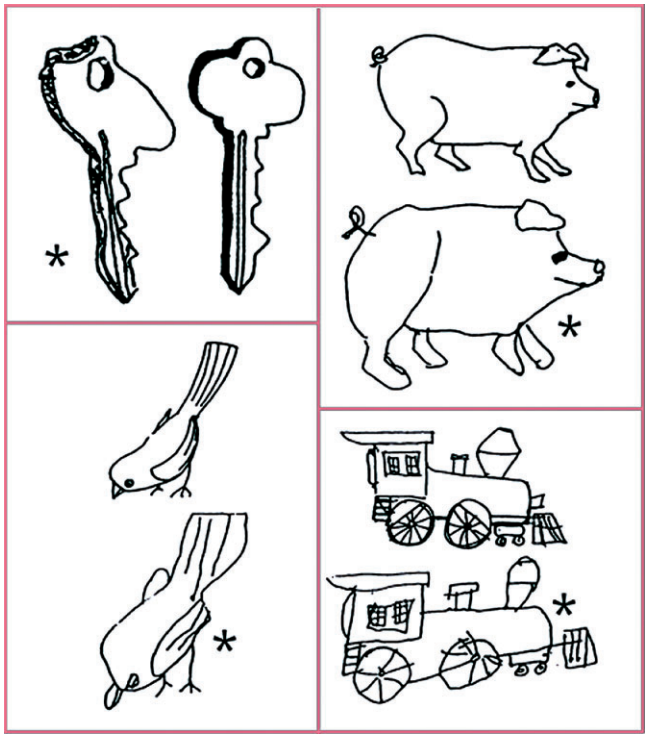

FIGURE 44.2 Pictures that a patient with associative visual agnosia did not recognize but was able to copy. Asterisks indicate the patient's copies. *From Rubens and Benson (1971).*

Object Recognition in Monkeys Depends on the Inferior Temporal Cortex

One of the earliest experimental studies on the role of the temporal cortex in visual recognition was that of Klüver and Bucy, who described in the 1930s what is now known as the Klüver–Bucy syndrome. When these researchers removed the temporal lobes of monkeys bilaterally, the monkeys demonstrated complex changes in visual, social, sexual, and eating behavior. There was significant impairment in their ability to recognize and/or discriminate visual stimuli. These changes in visual ability were not accompanied by any apparent loss of visual acuity. Subsequent research eventually identified the region now known as inferior temporal (IT) cortex as the critical area for producing the visual component of the syndrome. Damage to medially adjacent temporal-lobe regions (i.e., the amygdala) failed to produce visual deficits, but instead led to the social and sexual abnormalities. Monkeys with bilateral IT lesions are impaired both in learning to distinguish between different visual patterns or objects, and in retaining previously acquired visual discriminations. Figure 44.1 shows the location of this area in the macaque brain, relative to the areas implicated in agnosia in humans.

What type of stimulus representation is impaired after IT lesions? A great deal of research has been devoted to this question. Generally, such experiments measure whether monkeys can discriminate different stimuli, before and after experimental lesions in IT cortex—and from any such differences, object-processing mechanisms are inferred. A current summary might be that IT cortex represents aspects of the intrinsic shape of the stimulus that are useful for recognition (e.g., the salient features in a face and their relative positions), generalizing across idiosyncratic aspects of stimulus appearance that depend on specific viewing conditions (see later).

Position in the visual field (retinotopy) is one of these specific visual properties that is independent of object identity, and normal monkeys will easily generalize a visual discrimination learned in one part of the visual field to another. For example, if monkeys learn to tell apart stimuli in one half of visual space, they will easily be able to perform the discrimination when the same stimuli are presented to the other half of visual space. However, monkeys with IT lesions are impaired at this generalization; presumably they have lost representations that are invariant across visual field locations.

Retinal image size of a stimulus is a related visual property that depends on viewing conditions and not just intrinsic object geometry, and this is another perceptual distinction that is difficult for monkeys with IT lesions. For example, monkeys trained to discriminate between two disks of different absolute sizes are unable to perform the discrimination when those disks are presented at variable distances (hence with variable retinal image sizes). Instead, they respond on the basis of retinal size or distance. This result implies that representations within IT cortex normally encode the absolute size of an object, an intrinsic object property useful for recognition, rather than its distance per se or its retinal image size. Finally, variations in illumination prevent monkeys with IT lesions from seeing the equivalence of objects, implying that representations in IT cortex are unaffected by patterns of shadow and light falling on object surfaces.

Summary

Studies of brain damage in humans, and experimental lesions in monkeys, both point to the crucial role of the inferior temporal cortex during object perception and recognition. In both species, analysis of the ensuing deficits suggests that this region participates in creating and storing neural representations of the defining features and invariant aspects that identify a visual object or class of objects.

VISUAL PATHWAYS FOR OBJECT PROCESSING IN NONHUMAN PRIMATES

"What" versus "Where"—Dividing the Visual Cortex of Monkeys into Occipitotemporal and Occipitoparietal Pathways

Early evidence that the visual cortex is divided into separate processing streams was based on the contrasting

effects of inferior temporal and posterior parietal cortex lesions in monkeys. Inferior temporal lesions cause severe deficits in visual discrimination tasks, but they do not affect animals' performance on visuospatial tasks (e.g., visually guided reaching and judging which of two objects lies closer to a visual landmark). In contrast, parietal lesions do not affect visual discrimination ability but instead cause severe deficits on visuospatial performance. On the basis of behavioral results such as these, Ungerleider and Mishkin (1982) proposed the existence of two processing streams: an occipitotemporal or ventral processing stream for mediating the visual recognition of objects ("what" an object is) and an occipitoparietal or dorsal processing stream for mediating the appreciation of the spatial relationships among objects and the visual guidance toward them ("where" an object is). Goodale and Milner (1992) later proposed a modification of this model, emphasizing "perception" versus "action" for ventral and dorsal processing streams, respectively. More recently, it has been proposed that the dorsal stream can be further subdivided into three separate pathways subserving spatial working memory (occipitoparietal-prefrontal), visually guided actions (occipitoparietal-premotor), and navigation (occipitoparietal-medial temporal) (Kravitz, Saleem, Baker, & Mishkin, 2011). The dorsal processing pathways and their importance for spatial cognition are the topics of Chapter 45.

As described in Chapter 26, physiological studies of neuronal properties also support the functional distinction between ventral and dorsal pathways. Neurons within the ventral stream (in distinct modules within V1 and V2, area V4, and inferior temporal areas TEO and TE) respond selectively to visual features relevant for object identification, such as color, shape, and texture. Neurons within the dorsal stream (in other modules within V1 and V2, areas V3, V3A, middle temporal area MT, medial superior temporal area MST, and additional areas in the inferior parietal cortex) instead respond selectively to spatial aspects of stimuli, such as the direction and speed of stimulus motion. Such neurons also respond when the animal visually tracks a moving target. The remainder of this section describes the anatomy of the *occipitotemporal pathway* for object recognition.

The Object Recognition Pathway in Monkeys Consists of an Interconnected Set of Cortical Areas

In both monkeys and humans, cortical regions comprising the object recognition pathway lie directly adjacent to the primary visual cortex (V1) in the occipital lobe, extending progressively into more anterior and ventral portions of the temporal lobe (Fig. 44.3). The cortical analysis of objects begins in V1, where information about contour, orientation, color composition, and brightness is represented in subsets of neurons coding for each point in the visual field (see Chapter 26). Information from V1 projects forward to interdigitating thin, thick, and interstripe regions—within V2 (see Chapter 26). From the thin and interstripe regions in V2 (specialized, respectively, for color and form information, roughly speaking), neural signals proceed forward to area V4 on the lateral and ventromedial surfaces of the hemisphere and to a posterior inferior temporal area just in front of V4, area TEO. From both V4 and TEO, signals related to object form, color, and texture proceed forward to area TE, the last exclusively visual area within the ventral stream for object recognition. Together, areas TEO and TE constitute IT cortex.

Progressing forward along the occipitotemporal pathway from V1 to TE, there is a gradual shift in the nature of connectivity, which is significant for the eventual extraction of invariant object features. At successive stages, patterns of cortical projections become successively less topographic or "point to point." While connections from V1 to V2 maintain topographic order, the organization becomes looser between V2 and V4, and inputs to area TE from V4 and TEO retain no obvious retinotopic organization. Likewise, pathways interconnecting areas of the ventral stream on the two sides of the brain via the corpus callosum and/or the anterior commissure tend to be restricted to the representation of the midline of visual space early in the pathway, but their representation becomes more widespread at higher levels in the pathway. This loss of retinotopy within area TE means that single neurons respond to objects anywhere in the visual field. This evidence suggests that the initial explicit information about spatial position in the visual field ("retinotopy") has been converted to information about object identity, in at least some parts of IT cortex.

However, neural processing in the object recognition pathway is not a simple elaboration of information from lower-order to higher-order areas. At all stages, the neural connections are reciprocal, such that an area receiving feedforward projections from an area earlier in the ventral stream also provides feedback projections to that area. Long-range nonreciprocal connections, such as from area TE back to V1, also exist. On the one hand, feedforward projections provide bottom-up, sensory-driven inputs to subsequent visual areas, and severing these projections disconnects subsequent areas from their visual input. On the other hand, the precise functions of reciprocal, feedback projections are still unknown. Probably these feedback projections play a top-down role in vision (as in selective attention) by modulating activity in earlier areas of the ventral pathway (see Chapter 46). In addition to feedforward and feedback projections, there also appear to be "intermediate-type" projections that link areas at the same level of the visual hierarchy. These are seen most notably between areas of the dorsal and ventral streams. For example, area V4 is interconnected with

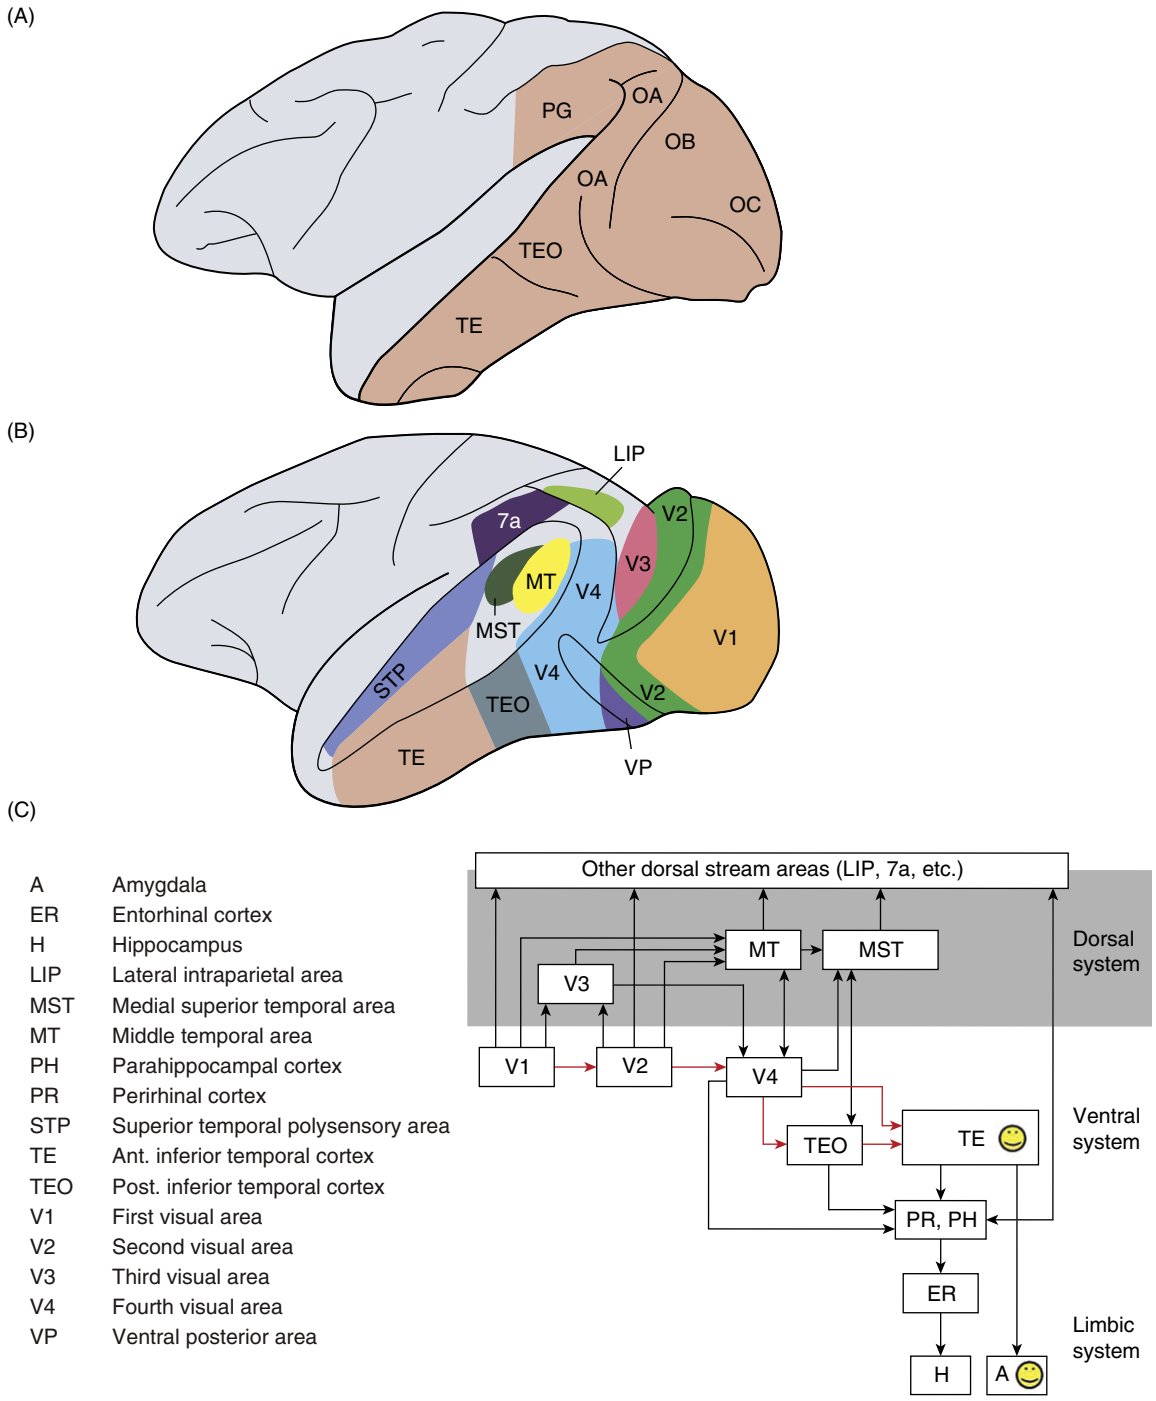

FIGURE 44.3 (A) Schematic diagram of the macaque monkey brain illustrating the two cortical visual system model of Ungerleider and Mishkin (1982). According to this model, there are two major processing pathways, or "streams," in the visual cortex, both originating in the primary visual cortex: a ventral stream, directed into the temporal lobe and crucial for the identification of objects, and a dorsal stream, directed into the parietal lobe and crucial for spatial perception and visuomotor performance. The shaded region indicates the extent of the visual cortex in the monkey, and the labels (OC, OB, OA, TEO, TE, PG) indicate cytoarchitectonic areas according to the nomenclature of von Bonin and Bailey. *Adapted from Mishkin, Ungerleider, and Macko (1983).* (B) A lateral view of the monkey brain illustrating the multiplicity of functional areas within both processing streams. (C) Some of the pertinent connections of the inferior temporal cortex with other cortical areas and medial temporal-lobe structures. Red lines indicate the main afferent pathway to area TE, which includes areas V1, V2, V4, and TEO. For simplicity, only projections from lower-order to higher-order areas are shown, but each of these feedforward projections is reciprocated by a feedback projection. Faces indicate areas in which neurons selectively responsive to faces have been found. *Adapted from Gross, Rodman, Gochin, and Columbo (1993).*

motion-sensitive areas MT and MST. Thus, an anatomical substrate exists for interactions between the two processing streams, and these might serve to integrate what an object is with where it is located.

All areas within the ventral stream also have heavy interconnections with subcortical structures, notably the pulvinar, claustrum, and basal ganglia. In addition, each ventral stream area also receives subcortical modulatory inputs from ascending cholinergic projections from the basal forebrain, and ascending noradrenergic projections from the locus coeruleus. These projections are thought to play a role in the storage of information in the cortex, and the influence of arousal on information processing, respectively. Finally, visual information is sent *from* IT cortex to the most ventral and anterior reaches of the temporal lobe, notably the perirhinal cortex and parahippocampal areas TF and TH. These regions in turn project, via the entorhinal cortex, to medial temporal-lobe structures, such as the hippocampus, which contribute to forming long-term memories of visual objects and their contexts (see Chapter 48). Information is also sent from IT cortex to the prefrontal cortex, which plays an important role in working memory, holding an object briefly in mind when it is no longer visible (see Chapter 50). Finally, there are direct projections from IT cortex to the amygdala, which is important for attaching emotional valence to a stimulus.

Summary

Areas along the occipitotemporal pathway of the monkey are organized hierarchically, proceeding from V1 > V2 > V4 > TEO > TE. At progressively higher stages of this hierarchy, there is a corresponding loss (or conversion) of retinotopic information, such that information about the spatial location of the object is gradually changed. In addition to this bottom-up information (supplied by feedforward projections from lower-order to higher-order visual areas within this pathway), there are also reciprocal, feedback projections from higher-order to lower-order visual areas. These latter projections are thought to play a top-down role in vision.

NEURONAL PROPERTIES WITHIN THE OBJECT RECOGNITION PATHWAY

Neurons along the Occipitotemporal Pathway are Sensitive to Increasingly More Complex Physical Features of Objects

The different cortical areas in the occipitotemporal pathway share a number of physiological characteristics. Consistent with a role in object recognition, all areas in the pathway contain populations of neurons sensitive to the shape, color, and/or texture of visual stimuli. However, at progressively higher levels, neurons have larger receptive fields and their stimulus selectivity is more complex to characterize. Thus, higher-order properties (consistent with invariant representation of objects) usually are attributed to neurons in higher tier areas. For instance, many V1 neurons function as local spatial filters, signaling the presence of contours at particular positions and orientations in the visual field. In contrast, an increasingly higher proportion of neurons in higher tier areas (e.g., V2 and beyond) apparently respond to *illusory* contours (i.e., contours implied by stimulus context and higher-order properties, not due to simple light-dark contrast) across increasingly larger regions of the visual field.

Additional higher-order, object-related properties are also seen at higher tier cortical levels. One of these properties is increasing stimulus invariance (see below)—namely, similar shape selectivity despite variations in the type of lower-order cues used to generate the shape (such as luminance, color, motion, etc.). Another of these properties is increasingly strong, silent suppressive zones surrounding the classical, excitatory receptive field of neurons. These zones are called silent because visual stimulation of them normally does not cause any change from the baseline activity of the neurons—although it can nevertheless powerfully affect responses to a stimulus placed in the classical receptive field. For example, many V4 neurons respond maximally to a stimulus only if it stands out from its background based on differences in form—as in the well-known perceptual phenomenon of figure/ground segregation, a computation that remains difficult to achieve in machine-based object recognition.

Farther forward along the occipitotemporal pathway there are further increases in the complexity of the critical features needed to activate many neurons. Connor and colleagues have demonstrated that neurons in V4 and the posterior portion of IT cortex (area TEO and posterior area TE) are responsive to single contours as well as particular combinations of contours (Pasupathy & Connor, 2002; Brincat & Connor, 2006). These neurons are often insensitive to the position of the contour(s) within a more complex object, indicating that they can participate in the coding of many different complex objects. The convergence of outputs from such neurons could potentially result in neurons selective for objects of even further complexity—which is precisely what is observed within anterior portions of the IT cortex. Specifically, neurons in the anterior two-thirds of IT cortex (area TE) are maximally activated by more complex arrangements of features, including intact objects and even faces.

At these highest levels, it can become very difficult to discover the optimal stimulus for a given single cell by simply testing various visual stimuli because the number of possible test stimuli is infinite. This experimental problem is related to the idea, developed sometime in the late

1960s, that every object would be coded by maximal firing of a single neuron in IT cortex; this was termed the "grandmother neuron" hypothesis because each "grandmother" was thought to cause maximal firing in a single neuron (Gross, 2002). Theoretically, if this neuron were to be destroyed, we should lose the ability to recognize our grandmother. This idea, which was controversial from its inception, is considered by most researchers to be overly simplistic: there simply are not enough neurons to represent all the different objects we can recognize.

Instead, a "population code" is more likely, in which each specific object (and perhaps each viewpoint; see Box 44.2) causes a correspondingly unique pattern of firing in multiple neurons that share connections and overlapping functional selectivity. This latter idea is supported by evidence suggesting that IT neurons are anatomically grouped into functionally similar patches, columns, or areas. Based on findings from single-unit and optical recording, Tanaka (1996) has suggested that IT neurons that respond to common visual features are grouped together into cortical columns that run perpendicular to the cortical surface (Fig. 44.4). This object-column model is similar to that for other well-known columns in early visual areas, which are selective either for orientation, ocular dominance, spatial frequency, or direction of motion. However in Tanaka's model, there is a continuous mapping of complex feature space within a larger region that contains several partially overlapping columns (Fig. 44.4), rather than just one periodic feature, such as orientation, mapped repeatedly. Newer evidence from functional magnetic resonance imaging in awake monkeys further supports the notion that neurons with common functional properties are grouped together within temporal cortex (Op de Beeck, Deutsch, Vanduffel, Kanwisher, & DiCarlo, 2008).

Thus, a given object is not represented by the activity of a single neuron, but by the activity of many neurons across different columns or regions (i.e., "population coding"). A significant benefit of combination coding over a sparse coding scheme (i.e., "The Grandmother Cell Hypothesis") is that it is much more flexible. It can provide robustness to changes in input and precision of representation. Although the image of an object projected on the retina changes in response to variations in illumination and viewing angle, the pattern of activity in IT cortex will be largely maintained, insofar as the clustering of neurons with overlapping but slightly different selectivity serve as a buffer to absorb such changes.

Invariant Representations in the Occipitotemporal Pathway

As described above, the precise nature of the visual information regarding a particular object reaching the retina can change dramatically due to changes in its position, distance, illumination, and orientation relative to the viewer. However, the identity of the object under examination doesn't change. The function of the occipitotemporal pathway can be defined in large measure as determining and encoding those *invariant* features of objects that are useful for recognition.

As one progresses forward from V1 to TE, receptive fields become larger and the retinotopic maps less precise. By area TE, receptive fields are large and bilateral, typically encompassing the central 20° or more—up to the entire visual field in far anterior TE. The large receptive fields of TE neurons signal the presence of a given feature, collection of features, or object, regardless of where they fall in the visual field. In other words, they exhibit invariance of stimulus coding across changes in retinal position (i.e., "position invariance"). Indeed, many neurons in TE show maintained selectivity for their "preferred" stimuli over more complex kinds of transformations, such as size, distance from the subject in depth, or degree of ambient illumination; thus, they show invariance over a number of the changes that normally take place as a moving object is viewed under naturalistic conditions.

Recent experiments by Li and DiCarlo (2008; 2010) have shown how stimulus invariance might be achieved through an associative learning process based on repeated exposures to the same stimulus under viewing conditions that change in a predictable way. Under normal viewing conditions, movement of an object (caused either by the object moving in space and/or by the eye moving relative to the object) will result in a rapid shift in the location of that object on the retina—and yet the identity of the object has not changed. Through repeated exposures, the brain can theoretically learn to associate these different retinal images as the same object in different positions, thus generating a *position invariant* representation. To test this hypothesis, Li and DiCarlo recorded from neurons in IT cortex while simultaneously presenting monkeys with an object at a fixed position from where the monkeys were currently looking. When the monkeys would move their eyes, the object would change to a new object. They predicted that if such an associative learning process were responsible for generating invariant representations, this manipulation should result in these two stimuli being confused as the same object—which was indeed the case. Initially, the neuron responded to the first object only and not the second. However, over time it responded to both, suggesting that the neuron perceived the two stimuli as the same. The ability of downstream neurons to discriminate between the two stimuli had been abolished. Subsequent experiments demonstrated the same effect for object size, suggesting that a similar mechanism might be responsible for generating *size invariance.*

BOX 44.2

THE ISSUE OF VIEWPOINT DEPENDENCE IN OBJECT RECOGNITION

Although we know something of the underlying anatomy and physiology, the mechanisms by which object recognition is accomplished by the brain have been a matter of heated debate. The pioneering theoretical work of Marr in the late 1970s set the stage for current theories, which can be divided into two main groups: object-based (view independent), and image-based (view dependent) theories.

Object-based theories propose that objects are represented in the brain as hierarchies of parts that are, to a large degree, independent of any particular viewpoint. One of the best known examples is Biederman's (1987) recognition by components (RBC), which postulates that objects can be defined as a set of 30 or so primitive shapes, called *geons* (Fig. 44.B1). In this theory, geons are three-dimensional component building blocks that, when combined, can describe any arbitrary object. For example, the telephone in Figure 44.B1 can be constructed from geons 1, 3, and 5. Critically, these geons were thought to be distinguished from one another on the basis of five properties: curvature, collinearity, symmetry, parallelism, and cotermination—properties integral to gestalt theory (Koffka, 1935). Neurophysiological support for object-based models of object recognition was supplied by researchers such as Tanaka and colleagues, who identified neurons in the temporal cortex of macaques selective for decomposed versions of real-world objects (Tanaka, Saito, Fukada, & Moriya, 1991; Tanaka, 1996).

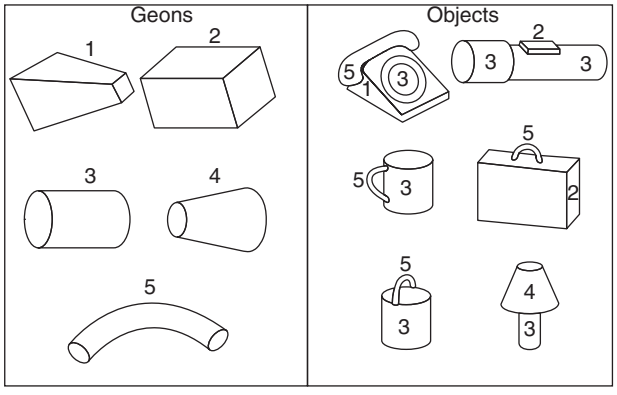

FIGURE 44.B1 Illustration of geons and how they are arranged to form objects. (Left) A given view of an object can be represented by an arrangement of simple primitive volumes, or geons, five of which are shown here. (Right) Only two or three geons are required to uniquely specify an object. The relations among the geons matter, as illustrated with the pail and cup. *From Biederman (1990).*

Object-based theories are considered to be "view-independent" because they rely on hard-coded representations of geons (or similar primitives) encompassing all possible orientations. *Image-based* (also known as *view-dependent*) theories, however, suggest that recognition is linked to the appearance of objects as originally seen. In other words, the brain is not thought of as storing a central, invariant representation of an object, but instead as storing information from multiple independent views (e.g., a view of the telephone as in the figure, but also an end-on or side view, a view from above, etc.). A potential problem with this idea is that it might seem that for reliable object recognition, stored representations for *all* views of objects would need to exist. The solution is to suggest that a small set of characteristic or *prototypical* views would suffice. Proponents of this approach have offered a variety of different theoretical normalization mechanisms for generalizing from unfamiliar views to the familiar, prototypical stored views (Bulthoff, Edelman, & Tarr, 1995). This theory does, however, argue that subjects will be better at recognizing objects when presented in familiar vs. unfamiliar views, which is indeed the case (Bulthoff & Edelman, 1992). This effect has also been demonstrated at the neuronal level. For example, in one study, monkeys were trained to recognize specific novel three-dimensional objects from any viewpoint after experience with a few prototypical views in a discrimination task (Logothetis, Pauls, & Poggio, 1995). After months of such training, the monkeys were found to have neurons in TE that exhibited strong selectivity for precisely those views on which the animal had been trained. These results support the view-dependent account of object recognition.

At first glance, object-based theories appear more compelling, as they attempt at the outset to solve the central problem associated with object recognition, namely reliable recognition despite variation in the precise retinal image. However, one serious challenge is how the brain chooses the correct structural interpretation among the possible ones, as a given set of geons may be compatible with several different objects. Psychophysical testing also indicates that object-centered encoding is not the whole story; studies have shown substantial and robust viewpoint effects even for extremely simple three-dimensional volumes resembling proposed geon primitives.

However, image-based approaches also face challenges. Image-based theories have been most successful in accounting for *exemplar-level* recognition; that is, discriminating

BOX 44.2 *(cont'd)*

between individual visually similar objects within a relatively homogeneous class of objects such as faces, cars, or birds. Though recognition at the exemplar level is often important, there is little question that so called *class-level* recognition actually constitutes much of the job of recognition. For example, for objects such as chairs, telephones, and toasters, we rarely need to discriminate two instances of the class and instead we learn to recognize such objects at a basic category or class level. Image-based models suggest that the brain represents the appearance of a specific individual example of an object from specific viewpoints, and thus seem unsuitable or unnecessary for class-level recognition. Moreover, even for a single exemplar, it is uncertain how many prototypical views are enough for robust recognition. One solution would be to store as many views of an object as possible so that new views would always be similar enough to some previously stored view. However, it is unclear that there can ever be sufficient memory to do so for all the objects that the observer becomes proficient at recognizing under varied conditions.

Face Selective Neurons in IT Cortex Sensitive to Socially Relevant Aspects of Facial Stimuli

One of the more striking characteristics of monkey temporal cortex is the presence of neurons with responses selective for face stimuli. First discovered by Gross, Bender, and Rocha-Miranda (1969), these neurons have received considerable attention, not only for their role in social communication but also for their significance to theories concerning object recognition. Early recording studies reported that face-selective neurons could be found throughout temporal cortex. However, recent studies combining functional neuroimaging with targeted neuronal recordings in nonhuman primates show that face-selective neurons are concentrated into small "patches," located primarily along the lower bank of the superior temporal sulcus and extending onto the adjacent IT gyrus (Tsao, Freiwald, Tootell, & Livingstone, 2006; Bell et al., 2011). It is currently hypothesized that these patches may be homologous to the face-selective regions in human cortex.

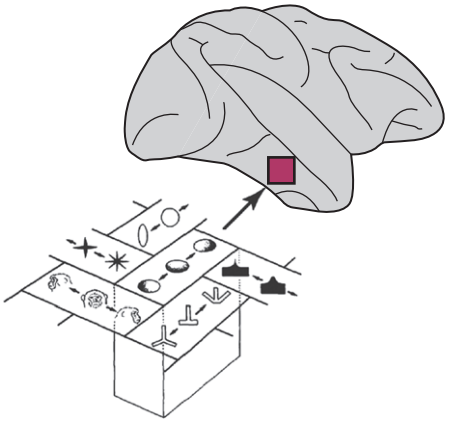

FIGURE 44.4 Schematic diagram illustrating the columnar organization in area TE of the monkey. Neurons with similar but slightly different selectivity tend to cluster in elongated vertical columns perpendicular to the cortical surface. Stimuli shown are examples of the critical features for the activation of single neurons in TE. Most neurons, as shown, require moderately complex features for their activation, although some can be driven by simpler stimuli, such as color, orientation, and texture. *Adapted from Tanaka (1996).*

Face-selective neurons vary in the degree and nature of their preference for face stimuli. Many respond well to both real faces and face pictures, but give little or no response to any other stimuli tested, including other complex objects, texture patterns, and images in which the features making up the face are rearranged or scrambled (Fig. 44.5). Thus, at least some face-selective neurons appear to be sensitive to very general or global aspects of a face, such as the prototypical arrangement of the eyes, nose, and mouth into a face-like configuration.

Other neurons respond to specific face components, such as the presence of eyes *per se*, the distance between the eyes, or the extent of the forehead, and some are sensitive to the direction of gaze of the eyes, which is an important social signal for both monkeys and humans. Other neurons are sensitive to different facial expressions (e.g., open-mouth threat vs. submissive or fearful faces). Finally, features relevant for facial identity discrimination have also been observed at the level of the individual neuron. Although such neurons may merely be sensitive to facial features, they are nonetheless likely to participate in circuits responsible for recognizing a particular individual. Indeed, recent work has demonstrated that electrical microstimulation of face-selective neurons biases object categorization in the direction of face perception, thus establishing a causal relationship between face-selective neurons and face perception (Afraz, Kiani, & Esteky, 2006).

These observations have led to the proposal that the primate temporal lobe has evolved specialized mechanisms for the encoding and recognition of biologically significant stimuli, especially faces. Are such regions innate, or recruited and trained as a result of experience? This is another form of the classical nature-versus-nurture question. Some evidence (e.g., preferential looking at faces in newborns) suggests that face-selectivity may indeed be innate, but experience likely improves such selectivity, as face recognition improves throughout development.

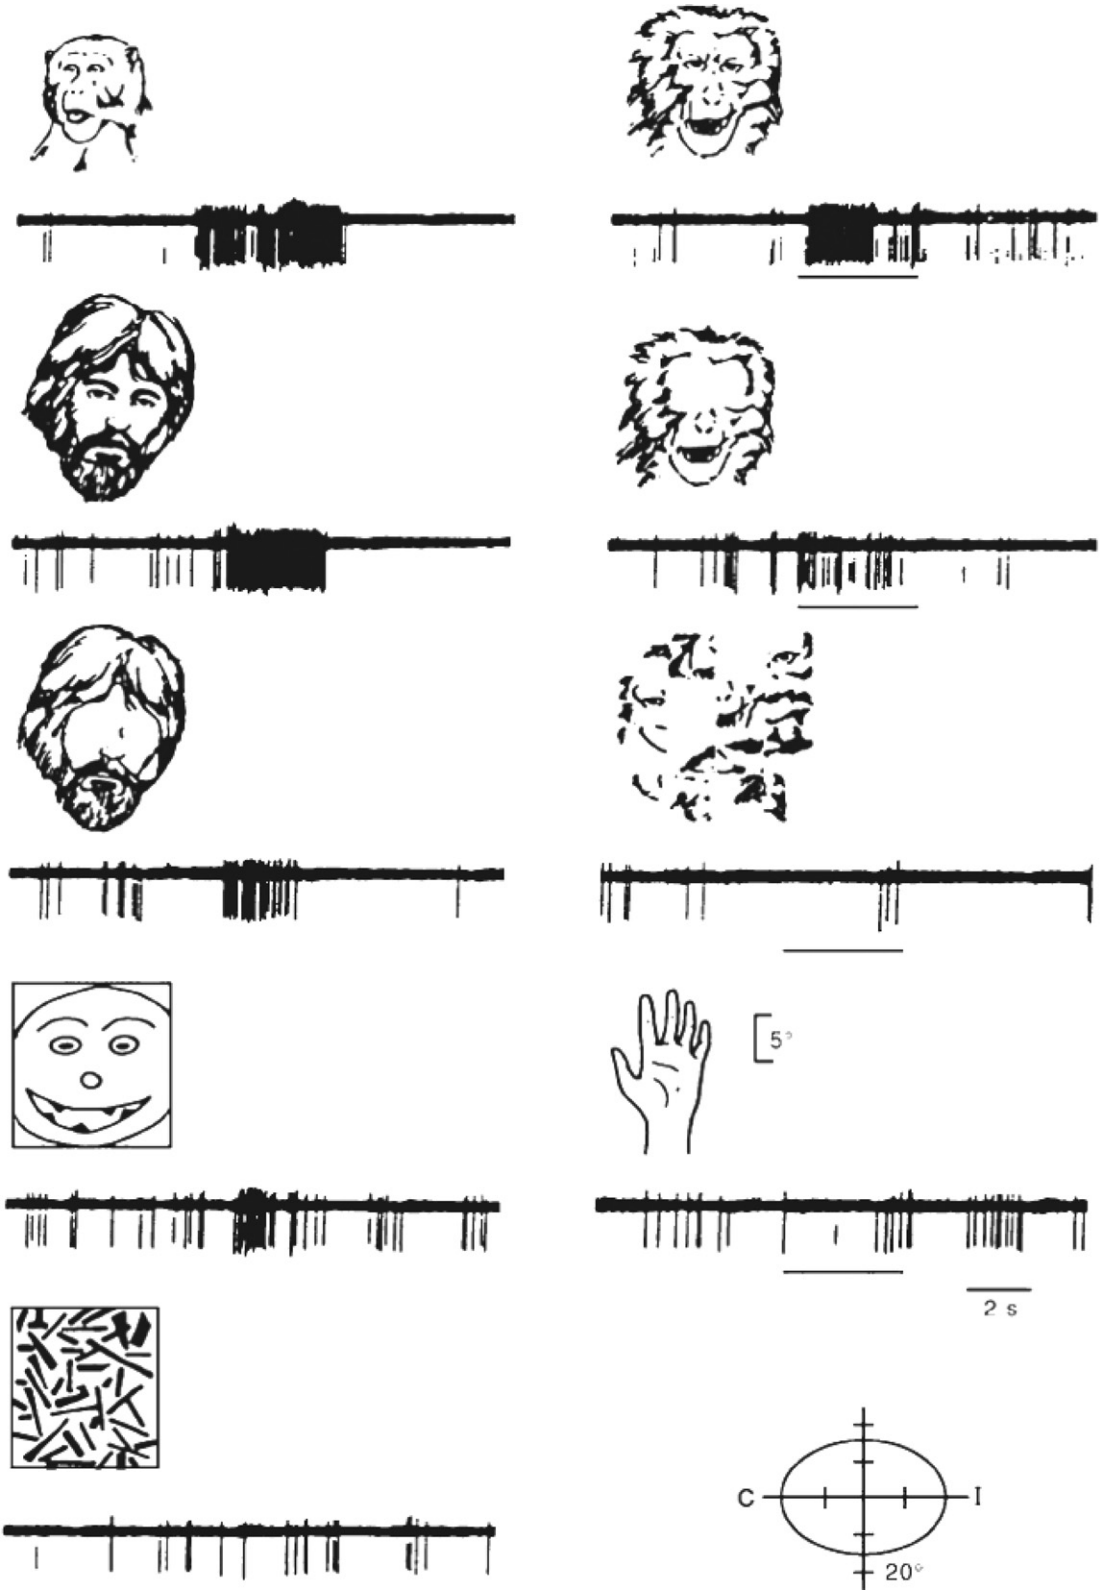

FIGURE 44.5 Activity of a neuron in the superior temporal sulcus that responded better to faces than to all other stimuli tested. Removing eyes on a picture or representing the face as a caricature reduced the response. Cutting the picture into 16 pieces and rearranging the pieces eliminated the response. All the unit records are representative ones chosen from a larger number of trials. The receptive field of the neuron is illustrated on the lower right. C, contralateral; I, ipsilateral visual field. *From Bruce, Desimone, and Gross (1981).*

Response Properties of Neurons in the Object Recognition Pathway are Affected by Experience

The previous sections illustrate how the object recognition pathway, especially area TE, represents features that are useful for recognition. Some neurons respond selectively to the salient features in a face, or their relative positions, while ignoring aspects of stimulus appearance that depend on viewing conditions, such as absolute size and luminance. However, in ecological terms, what is useful and salient within the image of an object or scene changes with experience and context, and these changes are reflected in the way the brain represents stimuli over time. To accommodate this need, neurons in IT cortex and the adjacent perirhinal cortex show effects of both recent viewing history and long-term experience with stimuli.

Experiments by Miller and Desimone (1994) have shown how short-term changes in response properties of neurons in temporal cortex encode aspects of both stimulus recency and short-term stimulus significance. For example, for many of these neurons, responses to an object that is presented repeatedly *decrease* in a systematic fashion, potentially signaling that the object has been seen recently. Such reduced signals may be useful for redirecting attention to novel objects. This kind of response decrement, termed *repetition suppression*, has been found both under anesthesia and for stimuli that an awake animal is trained to ignore. This same effect was later shown to persist over the course of an entire recording session (>1 hour), after hundreds of intervening stimuli. In essence, repetition suppression enables IT neurons to act as filters for novel stimuli. In contrast, if a monkey is trained to do a matching task in which it must hold a particular visual pattern in memory over a short delay, some temporal neurons *increase* their firing rates specifically when the to-be-remembered stimulus is recognized. This phenomenon, termed *mnemonic enhancement*, can be thought of as a mechanism in which bottom-up processing of the stimulus is affected by top-down, cognitive factors, namely, expectation of the relevant stimulus. Stimuli that are repeated but are not behaviorally relevant in the context of the task do not show this enhancement effect.

Experiments such as these demonstrate that the magnitude of neuronal responses can be affected by the experience of the subject with the stimulus and by its significance, at least in the short term. Other studies suggest that the kind of familiarity gained over longer periods of time—akin to the development of "expertise" as discussed later in the chapter—can also be reflected in the responses of TE neurons. For example, in monkeys that have been trained for as long as a year to discriminate between objects, more than 30% of the neurons show selectivity for those objects compared to untrained monkeys in which roughly 10% of the neurons show such selectivity (Kobatake, Wang, & Tanaka, 1998).

Some TE and perirhinal neurons can also represent the *history of association between objects* in the activity patterns they exhibit in response to members of a set of stimuli, as demonstrated by *paired associate* tasks, in which monkeys are trained to associate arbitrary stimuli with one another for reward. In one such experiment, monkeys were first shown one member of a learned pair and then were required to choose the associated "match" from a display of two stimuli while single-unit activity was recorded in anterior IT cortex (Sakai & Miyashita, 1991). Across all neurons recorded, the authors found neurons that responded best to stimuli that had been paired together during training. Neurons in temporal cortex developed conjoint selectivity (*pair coding*) for the members of associated pairs. It was shown that pair coding by TE neurons was decreased by surgically interrupting the feedback projections to them from the perirhinal and entorhinal cortices. Thus, return projections appear to play a specific role in associating objects because the pair-coding property depends on them.

Although associative learning effects typically have been seen in studies after weeks or months of training, there is evidence that small but detectable shifts in neuronal population selectivity occur after only a day or so of experience; this suggests that TE neurons tend to develop pair-coding properties more rapidly than previously thought (Erickson, Jagadeesh, & Desimone, 2000; Messinger, Squire, Zola, & Albright, 2001). Thus, the pattern of selectivity shown by TE neurons at any given moment in time may partly reflect a record of their exposure to stimuli seen together. Overall, TE circuits appear to represent not only complex visual features, but also the history of their meanings and relationships in a behavioral context.

Summary

At successive levels of processing along the occipitotemporal pathway, increasingly complex kinds of information about objects are extracted. In area TE of IT cortex, some neurons are preferentially responsive to faces and other biologically significant stimuli. In addition, TE neurons apparently extract some invariant aspects of objects. For example, TE neurons show similar selectivity for object shape, regardless of large changes in their retinal position, size, distance in depth, and degree of ambient illumination. Finally, as the result of experience, some TE neurons can come to represent novel objects and/or the associative relations between objects. This evidence tells us that neurons in higher-order visual areas are not necessarily limited to responding to a particular, unchanging set of features, but can adapt dynamically to different behavioral objectives, making them ideally suited as the neural substrate for object recognition.

FUNCTIONAL NEUROIMAGING OF OBJECT RECOGNITION

The Human Brain Also Has Ventral and Dorsal Processing Streams

The various visual impairments produced by focal lesions in clinical cases suggest that the human visual cortex, like that of the monkey, contains two anatomically distinct and functionally specialized pathways: the ventral and dorsal streams. One study demonstrated a double dissociation of visual recognition (face perception camouflaged by shadows) and visuospatial performance (maze learning) in two patients with lesions of the occipitotemporal and occipitoparietal cortex, respectively (Newcombe, Ratcliff, & Damasio, 1987). The specific clinical syndromes produced by occipitotemporal lesions can include visual object agnosia, prosopagnosia (an inability to recognize familiar faces, see below), and achromatopsia, or cortical color blindness. In contrast, syndromes produced by occipitoparietal lesions can include optic ataxia (misreaching), visuospatial neglect, constructional apraxia, gaze apraxia, akinetopsia (an inability to perceive movement), and disorders of spatial cognition. Interestingly, imagery disorders involving descriptions of either objects (especially faces, animals, and colors of objects) or spatial relations (geographic directions) are also dissociable following temporal and parietal lesions, respectively.

The development of functional brain imaging, including PET (positron emission tomography) and fMRI (functional magnetic resonance imaging), has made it possible to map the organization of the human visual cortex with far greater precision than is possible with human lesion studies, and without the confounding influence of compensatory responses to brain injury. This has provided researchers the tools to test hypotheses concerning visual perception in the intact human brain. Haxby, Horwitz, Ungerleider, Maisog, Pietrini, and Grady (1994) used positron emission tomography (PET) to demonstrate that humans, like monkeys, show two visual pathways: a dorsal or occipitoparietal pathway, stretching from V1 through extrastriate to parietal cortex, which is primarily concerned with visuospatial processing, and a ventral or occipitotemporal pathway, stretching from V1 through extrastriate to temporal cortex, which is primarily concerned with object processing (Fig. 44.6). These findings indicate the existence in humans, as in monkeys, of two functionally specialized and anatomically segregated visual processing pathways. They further suggest the extensions of each into the frontal lobe, which plays a role in working memory for objects and their spatial locations (see Chapter 50).

The "Building Blocks" of Object Recognition in Human Cortex Include Early Visual Areas and the Lateral Occipital Complex

Functional neuroimaging studies have revealed a number of distinct visual areas within the ventral and dorsal streams in humans. Many of these areas appear to be equivalent (and perhaps homologous) to specific monkey visual areas, including V1, V2, V3, V3A, V4, and the middle temporal area (MT). As in monkeys, most of these areas have been defined on the basis of retinotopic maps (Sereno et al., 1995). Area MT, a small area with somewhat disorganized retinotopy, instead has been defined on the basis of its distinctive functional properties (strong selectivity for visual motion and direction) in both human neuroimaging and single-unit recordings in macaque.

As described earlier, receptive field size increases, and stimulus requirements become more stringent, as one progresses from V1 through various stages of the ventral stream. For instance, single neurons in macaque IT cortex do not respond to "scrambled" versions of object images (e.g., Fig. 44.5). To test for analogous regions in human visual cortex, Malach et al. (1995) compared responses evoked by a range of images to those evoked by "scrambled" versions of those same images, while attempting to equate several image properties (such as size and contrast). Regions responding more to objects than to scrambled stimuli were interpreted as being involved in object-related processing; collectively these regions were named the lateral occipital complex (LOC) because of their anatomical location (Fig. 44.7).

A number of fMRI findings suggest that the LOC is an important stage in human object processing. First, whereas early visual areas V1–V3 respond similarly to intact, recognizable stimuli and highly scrambled, unrecognizable pictures (scrambled pictures tend to elicit even stronger responses), the LOC *exhibits a high sensitivity to image scrambling*. Second, a fourfold change in visual object size does not affect the LOC activation, although it changes some stimulus properties greatly (e.g., local contrast); responses in the LOC also exhibit some invariance to changes in image position. Third, the LOC responds to multiple visual cues. For example, the shape of an object can be defined by luminance, by texture, or by motion cues alone; objects defined by any one or more of these cues reliably evoke responses in the LOC. Fourth, objects that vary widely in their recognizability (e.g., famous faces and unfamiliar three-dimensional abstract sculptures) produce similar activations in the LOC. Together, these findings indicate that the LOC is an intermediate link in the processing of objects; that is, a stage following low-level processing and preceding object-processing stages that involve memory.

Summary

Evidence from lesion studies and neuroimaging studies confirms the existence in humans, as in macaques, of two visual processing pathways: a ventral stream for object

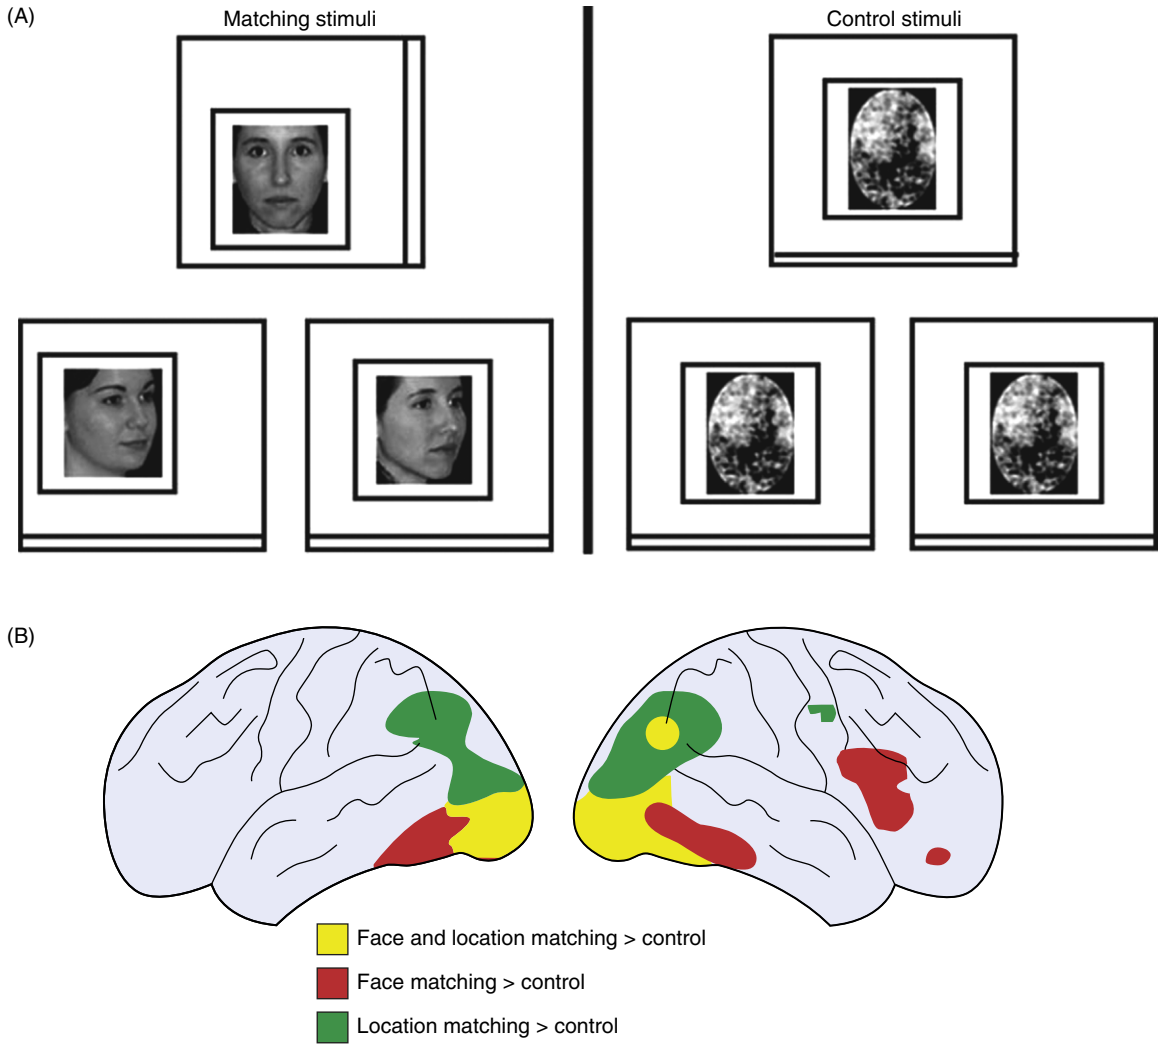

FIGURE 44.6 Ventral and dorsal processing streams in the human cortex, as demonstrated in a PET imaging study of face and location perception. (A) Sample stimuli used during the experiment. (Left) Stimuli for both face and location matching tasks. During face matching trials, subjects had to indicate with a button press which of the two faces at the bottom was the same person shown at the top. In this example, the correct choice is the stimulus on the right. During location matching trials, subjects had to indicate with a button press which of the two small squares at the bottom was in the same location relative to the double line as the small square shown at the top. In this example, the correct choice is the stimulus on the left. (Right) Control stimuli. During control trials, subjects saw an array of three stimuli in which the small squares contained a complex visual image. In these trials, which controlled for both visual stimulation and finger movements, they alternated left and right button presses. (B) Areas shown in red had significantly increased activity during the face matching but not during the location matching task, as compared with activity during the control task. Areas shown in green had significantly increased activity during the location matching but not during the face matching task, as compared with activity during the control task. Areas shown in yellow had significantly increased activity during both face and location matching tasks. *Adapted from Haxby et al. (1994).*

vision and a dorsal stream for spatial vision. Within the ventral stream, early visual areas, including V1–V4, are organized retinotopically and appear to be homologous to areas studied in monkeys. The LOC appears to play an important role at the next stage of processing, where general object shape is processed. Activation of the LOC is highly sensitive to image scrambling, but less sensitive to variations in image size or the visual cues that define the shape of an object. Activation of the LOC, however, is not sensitive to object recognizability, suggesting that it precedes processing stages that involve memory.

PERCEPTION AND RECOGNITION OF SPECIFIC CLASSES OF OBJECTS

Prosopagnosia is a Specific Deficit of Face Recognition

Evidence from neuropsychology and neurophysiology suggests that certain kinds of objects may have special significance to primates. *Prosopagnosia*, a selective deficit in recognizing familiar faces, has been known since at least the end of the nineteenth century. Although patients with

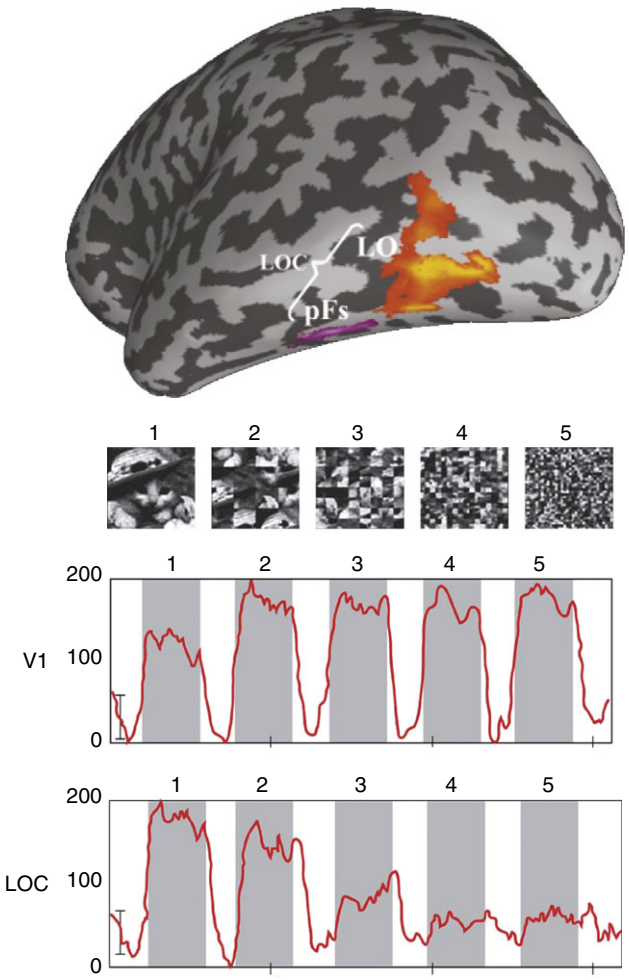

FIGURE 44.7 Shape processing in the lateral occipital cortex (LOC). (Top) Inflated view of the human brain showing the location of the LOC. *Adapted from Malach, Levy, and Hasson (2002).* (Middle) Visual stimuli that were used to investigate the effects of image scrambling on activity in the LOC, as measured by fMRI. Subjects viewed the stimuli and were instructed to covertly name them, even the scrambled images. Stimulus 1 is the original image, and stimuli 2–5 are increasingly scrambled. (Bottom) fMRI time series illustrating the averaged activations in V1 and the LOC to each of the images shown above. Note that the LOC is very sensitive to image scrambling, whereas V1 is not. *Adapted from Grill-Spector et al. (1998).*

this syndrome are aware that faces are faces (i.e., they know the basic stimulus category), they fail to reliably identify (or even achieve a sense of familiarity from) the faces of coworkers, family members, famous persons, and other individuals previously well known to them. Typically, prosopagnosics also have trouble forming memories of new faces, even if other new objects can be learned. Because the voice of a visually unrecognized person usually enables the patient to identify and feel familiar with that person, prosopagnosia (face agnosia) appears to be a specifically visual impairment.

Since the 1980s, a number of cases with prosopagnosia have come to autopsy. The damage common to these lay within the *lingual and fusiform gyri* (Fig. 44.1), ventrally and medially within the cortex at the occipitotemporal junction. In all such cases, this area (or at least the underlying white matter) was damaged bilaterally, and consequently bilateral damage was thought by many to be a necessary precondition for prosopagnosia. Additional cases with prosopagnosia and right cortical damage alone, along with the results of neuroimaging studies (see later), have reopened the debate over the locus of the critical lesion in prosopagnosia.

Several recent reports of developmental prosopagnosia have provided invaluable information concerning the perceptual deficit observed in these patients. Developmental prosopagnosia is characterized by severely impaired face recognition in individuals with no detectable brain damage (i.e., presumably intact visual systems). Many developmental prosopagnosics have normal or relatively good object recognition, indicating that their impairments are not the result of deficits to a unitary visual recognition mechanism. Indeed, extensive testing of particular individuals has revealed especially pure face processing deficits (Duchaine & Nakayama, 2006). In such individuals, the results strongly suggest that faces are recognized by a content-specific, face-processing mechanism. However, it should be noted that neuroimaging studies have demonstrated a variety of neural profiles in developmental prosopagnosia, which is consistent with behavioral studies indicating that, in general, developmental prosopagnosia is a heterogeneous disorder (i.e., in some cases deficits are not restricted to faces).

Neuroimaging and Electrophysiological Studies Reveal Neural Substrates of Prosopagnosia

The existence of prosopagnosia suggests that certain regions within the ventral stream should be very responsive to faces. This is exactly what has been observed in neuroimaging studies. For example, early PET and fMRI studies revealed a region on the fusiform gyrus of the right hemisphere that is significantly more active when subjects view faces, compared to when they view common nonface objects (Fig. 44.8). Kanwisher, McDermott, and Chun (1997) called this area the "fusiform face area" (FFA). The FFA is more active during face matching than location matching, and during the viewing of faces than during the viewing of scrambled faces, letter strings, or textures. Other face-selective regions have since been identified in ventral occipital cortex (the "occipital face area," OFA), the superior temporal sulcus, and the anterior portion of the temporal lobe. Notably, damage to one or more of these areas can lead to deficits in face processing, including prosopagnosia.

Evidence from electrophysiological recordings in patients with implanted electrodes (as part of the preparation for neurosurgery to treat epilepsy) also localizes

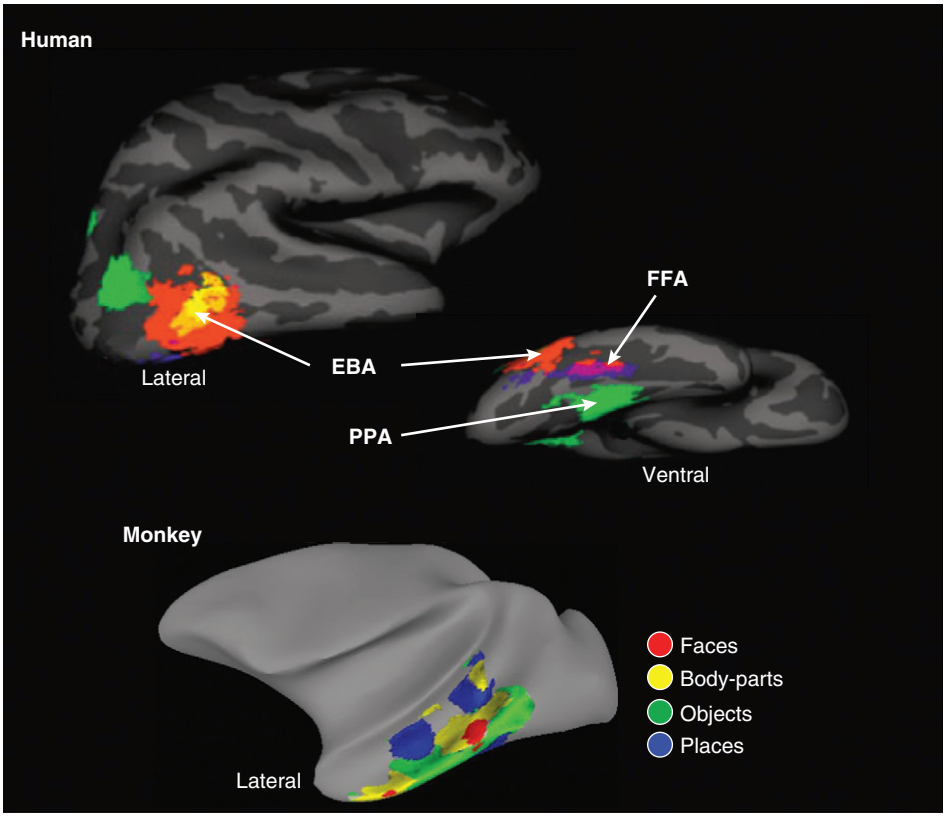

FIGURE 44.8 Category-selective regions in the human and monkey as revealed by fMRI. (Top) Regions in the human brain significantly more activated by faces (fusiform face area, "FFA"), body parts (extrastriate body area, "EBA"), and places (parahippocampal place area, "PPA"). *Adapted from Spiridon, Fischl, and Kanwisher (2006).* (Bottom) Similar regions in the monkey brain. *Adapted from Bell et al. (2009).*

face-selective processing to the ventral occipitotemporal cortex (Allison, Puce, Spencer, & McCarthy, 1999). A large evoked potential, called the *N200* because it occurs roughly 200 ms after stimulus onset, is generated in small regions (i.e., typically at only one electrode within an electrode array) in the ventral occipitotemporal cortex. The N200 amplitude is largest in response to full faces and decreases progressively to eyes, face contours, lips, and noses viewed in isolation. Interestingly, a region just lateral to face-selective N200 sites is more responsive to internal face parts than to faces, and some sites in ventral occipitotemporal cortex appear to be face-part specific. Other electrophysiological approaches have been applied to the study of face processing in humans. Liu, Harris, and Kanwisher (2002) used magnetoencephalography (MEG) to associate two separate evoked potentials (M100 and M170) in the occipitotemporal cortex to different stages of face processing: face detection and face identification.

Ventral Pathway Contains Regions Specialized for Other Visual Categories

Subsequent neuroimaging studies have identified regions selective for other visual categories. Medial to the fusiform gyrus is an area within parahippocampal cortex that is significantly more active when subjects view complex scenes (such as rooms, landscapes, landmarks, and city streets) compared to when they view objects, faces, or other kinds of visual stimuli. This region has been named the parahippocampal place area (PPA) (Fig. 44.8) (Epstein & Kanwisher, 1998) and damage to the lingual/parahippocampal region may result in landmark agnosia. Along the lateral occipitotemporal cortex (near the middle occipital gyrus), an area selectively activated by images of human body-parts (such as an isolated foot or arm) relative to viewing objects has been identified (Downing, Jiang, Shuman, & Kanwisher, 2001; Orlov, Makin, & Zohary, 2010). This region has been called the extrastriate body area (EBA) (Fig. 44.8). An additional body-part selective region has been identified in the fusiform gyrus (the "fusiform body area," FBA) (Schwarzlose, Baker, & Kanwisher, 2005).

Studies of brain lesions in patients suggest that there is a specialized region for the processing of *written words* in the brain. Patients with *alexia* cannot read despite intact visual capabilities, and despite their ability to understand spoken language and to write. Alexia can therefore be conceptualized as essentially a visual agnosia for verbal material. Accordingly, an area has been discovered near the fusiform gyrus in the occipitotemporal and inferior occipital sulci (Cohen et al., 2000). This "visual word form

area" (VWFA) is selectively activated by letters, words, and to a lesser degree, nonsense letterstrings. It is found almost exclusively in the left hemisphere, the same hemisphere as Broca's and Wernicke's areas—regions intimately involved in speech and language comprehension. Importantly, because we are not born with knowledge about written words, the existence of VWFA indicates that at least some category-specific cortex must arise as a result of experience.

Collectively, this evidence suggests that the human visual system is organized such that some object categories are represented in a relatively specialized fashion: faces, places, body parts, and words appear to have dedicated neural mechanisms for their representation. Similar specialization has been observed in the macaque brain using fMRI. Specifically, presenting images of faces (human or monkey), body-parts (human or monkey), objects, or places activates discrete areas within the inferior and ventral temporal cortex (Fig. 44.8) (Tsao, Freiwald, Knutsen, Mandeville, & Tootell, 2003; Pinsk, DeSimone, Moore, Gross, & Kastner, 2005; Pinsk et al., 2009; Bell, Hadj-Bouziane, Frihauf, Tootell, & Ungerleider, 2009). As described above, neuronal recordings from these regions have revealed disproportionately high concentrations of neurons selective for these categories (Tsao et al., 2006; Bell et al., 2011). Recent developments in fMRI methods have further demonstrated that these regions form interconnected networks specialized for processing stimuli from different visual categories (see Box 44.3).

Category-Selective Regions Linked to Conscious Perception

The existence of specialized regions in the temporal cortex clearly argues for a strong role in visual perception—but what precisely is this role? One possibility, for which there is mounting evidence, is that these areas are not simply responding to the visual features that comprise stimuli from a given category, but that they are involved in the *conscious perception* of these stimuli. In one neuroimaging study, the differential sensitivity of the ventral cortex to different visual stimuli was explored in a *binocular rivalry* paradigm in which different stimuli (faces and houses) were presented to the right and left eyes (Tong, Nakayama, Vaughan, & Kanwisher, 1998) (Fig. 44.9). During binocular rivalry, the resulting percept is not a combination of the two stimuli. Instead, subjects report the actual percept to alternate between the two stimuli, every few seconds—even though the dual retinal stimulation is kept constant. As expected, subjects' perceptions fluctuated between

BOX 44.3

LINKING CATEGORY-SELECTIVE REGIONS INTO SPECIALIZED NETWORKS

The application of fMRI to the study of object perception has resulted in the identification of a number of regions within the occipitotemporal cortex sensitive to particular categories of visual stimuli, including faces, body parts, and places. In virtually all cases, multiple regions for each category have been observed; suggesting the existence of separate *networks* specialized for the processing of specific categories. Until recently, demonstrating connectivity between individual nodes within these putative networks would have required classical anatomical tracer studies. However, recent developments in MRI analytic techniques have provided researchers with the opportunity to study connectivity in the intact brain.

Resting state or functional connectivity (FC) analysis, for example, measures the degree to which fMRI activation in one area is correlated with activation in another, and can be used to identify not only possible connections between areas but also offer insight as to the nature of the interactions (see Deco, Jirsa, & McIntosh, 2011). Zhu, Zhang, Luo, Dilks, and Liu (2011) used FC to show how the correlation between activation in FFA and OFA was greater during face recognition tasks as compared to object recognition tasks. Nummenmaa, Passamonti, Rowe, Engell, and Calder (2009) used a similar approach to show how face-processing networks interact with the oculomotor network in the frontal cortex during direct shifts in attention induced by changes in gaze direction.

Diffusion tensor imaging (DTI), which can be used to identify white matter tracts (see Johansen-Berg & Rushworth, 2009), has been used to show how face perception ability relates to the viability of connections between the various face-selective regions in human temporal cortex. Patients suffering from congenital prosopagnosia show reduced white matter volume in the fiber tracts travelling through the fusiform gyrus to the anterior temporal cortex (Thomas, Avidan, Humphreys, Jung, Gao, & Behrmann, 2009). Finally, in the nonhuman primate, fMRI can be used in conjunction with microstimulation to visualize connections between functionally related regions. Moeller, Freiwald, and Tsao (2008) applied microstimulation to fMRI-identified face patches to show that the nonhuman primate brain contains an interconnected network of regions dedicated to face processing.

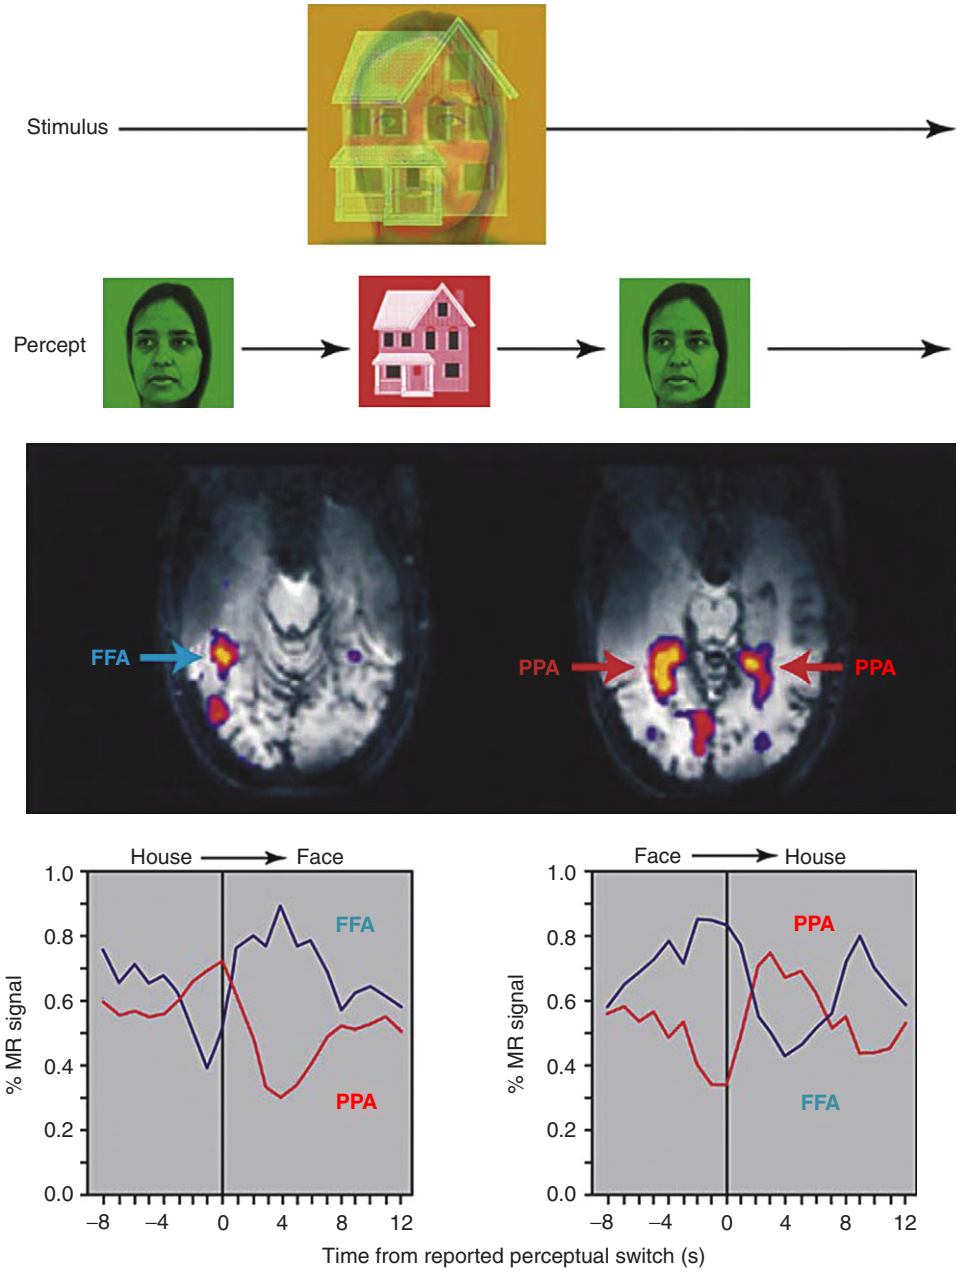

FIGURE 44.9 Design and results from an fMRI experiment on binocular rivalry. (Top) The illustration shows the ambiguous face/house stimulus used to produce rivalry. When viewed through red and green filter glasses, only the face could be seen through one eye and only the house through the other eye. This arrangement led to binocular rivalry, with a face percept alternating with a house percept every few seconds. (Middle) Two adjacent axial slices through the brain of a single subject showing, in the left slice, the area on the fusiform gyrus that responded more to faces than houses (FFA) and, in the right slice, the area on the parahippocampal gyrus that responded more to houses than to faces (PPA). In the slices shown, left is the right hemisphere and right is the left hemisphere. The scale at right indicates (Bottom) fMRI time series showing FFA and PPA activity for a single subject illustrating that the activity in these two regions correlated with the subject's visual percept. FFA, fusiform face area; PPA, parahippocampal place area. *Adapted from Tong et al. (1998).*

faces and houses. Critically, while changes from house to face percepts were accompanied by increased activation in the right FFA, changes from face to house percepts led to decreased activation in the FFA.

Summerfield, Egner, Mangels, and Hirsch (2006) demonstrated that FFA responds even during incorrect perceptual judgments concerning faces. On each trial, subjects were presented with either a degraded face or house and were required to report which of the two categories was presented. Predictably, PPA was activated when subjects correctly indicated seeing a house, and FFA and OFA were activated when subjects correctly indicated seeing a face. However, FFA activation was also increased when subjects *incorrectly* reported seeing a face when, in fact, a house was presented. This suggests that activation in FFA is related more to the *percept* than to the physical stimulus itself.

Artificially influencing these regions can directly impact perception. Afraz et al. (2006) trained monkeys to perform a categorization task where they were presented with degraded images of faces and non-face objects. By applying electrical microstimulation to small clusters of neurons located in inferior temporal cortex (likely in the vicinity of the face-selective patches, see above), they were able to bias the monkey's decision toward faces irrespective of the stimulus presented.

Alternative Proposals to Category-Specific Representations

It has been proposed that the FFA is specialized not for the processing of faces *per se* but rather for the processing of objects with which one has acquired expertise (Gauthier, Williams, Tarr, & Tanaka 1998; Gauthier, Tarr, Anderson, Skudlarski, & Gore, 1999). The idea that expertise underlies responses in ventral temporal cortex raises an important distinction between two interpretations. One interpretation suggests that activation is based on visual features (e.g., the visual features composing a face, such as eyes, nose, and mouth). Another interpretation emphasizes the *processes* associated with perceiving or recognizing objects. In this latter view, the ventral stream contains areas that are best suited for different computations, which may be recruited as one acquires expertise with specific types of visual objects. This might involve encoding subtle differences between visually similar objects or, conversely, finding underlying similarities between visually dissimilar objects. In particular, the expertise view may help explain why some patients with prosopagnosia may also have associated deficits in areas of acquired expertise, such as a show dog expert who has lost the ability to differentiate breeds or a farmer who has lost the ability to recognize the cows in his herd. According to another alternative framework, the functional architecture of the ventral stream is viewed not as being composed of category-specific regions but instead as containing a distributed representation of information about object form. Consistent with this hypothesis, several fMRI studies have shown how different categories can be associated with individual patterns of response across the ventral temporal cortex in a highly consistent spatial arrangement across subjects (Ishai, Ungerleider, Martin, Schouten, & Haxby, 1999; Haxby, Gobbini, Furey, Ishai, Schouten, & Pietrini, 2001). Moreover, it is further possible to accurately identify which stimulus was presented to a subject based on the elicited pattern of fMRI activation (e.g., Kay, Naselaris, Prenger, & Gallant, 2008). In this view, the representation of an object is not restricted to a region that responds maximally to that object, but rather is distributed across a broader expanse of cortex. Within this distributed system, however, the representation of faces would be less extensive as compared to the representation of nonface objects, helping explain why it is possible for lesions to produce prosopagnosia while leaving the recognition of nonface objects largely intact.

Object Knowledge Is Stored in a Distributed Network of Cortical Areas

Although the distinction between perception and memory might seem sharp, in reality these two processes are intimately connected. Indeed, each time one identifies an object; one implicitly retrieves stored knowledge about that object. In other words, identifying an object necessarily implies knowing what that object is. Further, it is generally believed that the same neural tissue devoted to object processing also participates in the storage of the long-term representations of objects. For example, when a subject mentally imagines faces or houses (requiring the retrieval of stored object representations from long-term memory), the same patterns of activation across ventral temporal cortex are seen as those observed when actually viewing faces or houses. Object knowledge implies not only familiarity with the shape of an object, but also other attributes, such as its typical color and function. For example, how does one know that bulldozers are usually yellow and are used for digging? One neuroimaging study that examined this question asked subjects to name either the associated color or the associated action in response to the presentation of black and white line drawings of objects (Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995). By associated action the investigators meant the typical motion associated with an object, such as the motion produced by the arm of the bulldozer digging. Results showed that the generation of color names associated with objects selectively activated a region in the ventral occipital cortex just in front of the area involved in the perception of color, whereas the generation of action names activated a region dorsally in the middle temporal gyrus just in front of the area involved in the perception of motion. These findings suggest that information about the different attributes of an object is not stored in a unified fashion in any single area of the cortex. Rather, object knowledge seems to be stored in a distributed fashion such that information about specific attributes is stored close to the specific regions of the cortex that mediate the perception of those attributes. These neuroimaging results provide a basis for understanding category-specific disorders of knowledge resulting from patterns of focal brain damage.

This type of deficit, seen most commonly for animals and tools, involves a selective difficulty in naming and retrieving information about objects from a single category. If the distinction between different categories of objects, such as animals and tools, is dependent on access to information about different types of attributes, and if such attributes (e.g., form, color, motion and object-use associated motor movements) are stored in separate regions of the brain, then one may find a category-specific deficit depending on the site of the lesion. Indeed, consistent with neuroimaging data, it has been found that the locations of lesions in patients with impaired recognition and impaired naming of drawings of animals included the medial aspects of the occipital lobe, nearly the same region active during animal naming. In contrast, the locations of lesions in patients with impaired recognition and

impaired naming of drawings of tools all included the middle temporal gyrus, nearly the same region active during tool naming (Tranel, Damasio, & Damasio, 1997). It is important to note that the impairment in patients with category-specific deficits is not limited to visual recognition. These deficits occur when knowledge is probed visually or verbally, and therefore they reflect disorders of stored knowledge and not simply disorders of perception.

Summary

Prosopagnosia, a selective deficit in recognizing faces, is associated with damage to the occipitotemporal cortex, including the fusiform gyrus. Consistent with this impairment, neuroimaging and electrophysiological studies have demonstrated that the fusiform gyrus responds selectively to faces and that this activation is linked to face perception. Although these findings suggest the existence of a specialized region for processing faces, an alternative interpretation is that the fusiform gyrus performs specialized computations associated with perceiving certain objects, including but not limited to faces. Such computations would presumably apply to many objects with which one has expertise. Moreover, the existence of a region in the left occipitotemporal cortex selectively activated by letter strings and words demonstrates the role of experience in shaping the functional architecture of the object recognition pathway.

OVERALL SUMMARY

Early studies of brain damage in humans and lesions in monkeys pointed to the crucial role of tissue in the ventral parts of the temporal cortex for object perception and recognition. After many decades of intensive research, one can now say that the ventral portions of the temporal cortex form the last stations of an occipitotemporal ventral pathway, beginning in the primary visual cortex and progressing through multiple visual areas beyond it. In macaque monkeys, important regions for object perception and recognition include areas TEO and TE of the inferior temporal cortex. In humans, homologous circuits appear to exist in both occipital and temporal regions, including the lateral occipital complex, the fusiform gyrus, and nearby regions in the ventral temporal cortex.

Single-unit recording studies in monkeys show a progressive increase in the complexity of object features needed to "trigger" neurons at progressively more anterior stations in the occipitotemporal pathway. Many TE neurons show preservation of their selectivity over transformations that change the physical stimulus, such as retinal position, size, distance in depth, and degree of ambient illumination. At the highest levels of the pathway, within area TE, some neurons are preferentially responsive to faces and other biologically significant stimuli.

More recently, neuroimaging and electrophysiological studies in humans with implanted electrodes have also shed light on the mechanisms by which the primate brain represents objects. Descriptions of prosopagnosia, a selective deficit of face recognition that is associated with damage to ventral occipitotemporal cortex, foreshadowed discoveries of cortical zones that are activated preferentially by face stimuli. At the same time, selectivity for letter strings and even for learned arbitrary stimuli has suggested that experience also influences activity in the ventral pathway and, in the long term, may tune representations. Finally, more general knowledge about objects (what they are used for and how to manipulate them) appears to be stored across a distributed network of sensory and motor cortical areas.

CHAPTER

45

Spatial Cognition

As we move through the world, new visual, auditory, vestibular, and somatosensory inputs continuously impinge on the brain. Given such constantly changing input, it is remarkable how easily we are able to keep track of where things are. We can reach for an object, look at it, or kick it without making a conscious effort to assess its location. We understand the arrangement of parts in an object. We know automatically where we are in the environment and how to get from where we are to where we want to go. How is it that we can achieve the effortless mastery of space that underlies these abilities? This chapter outlines the contributions of brain areas in the parietal, frontal, and temporal lobes to the generation of actions in space, the understanding of spatial relations and navigation in the world.

NEURAL SYSTEMS FOR SPATIAL COGNITION

Dorsal Stream Visual Areas Send Spatial Information to Parietal Cortex

Within the cerebral hemispheres, visual information is processed serially by a succession of areas beginning with the primary visual cortex of the occipital lobe. Within this hierarchical system, there are two parallel chains, or streams, of areas: the ventral stream, leading downward into the temporal lobe, and the dorsal stream, leading forward into the parietal lobe (Ungerleider & Mishkin, 1982) (see Chapter 44). Although the two streams are interconnected to some degree, it is a fair first approximation to describe them as separate parallel systems. Areas of the ventral stream play a critical role in the recognition of visual patterns, including faces, whereas areas within the dorsal stream contribute selectively to conscious spatial awareness and to the spatial guidance of actions, such as reaching and grasping. Dorsal stream areas have several distinctive functional characteristics, including containing a comparatively extensive representation of the peripheral visual field and being specialized for the detection and analysis of moving visual images. These traits would be expected in any system processing visual information for use in spatial awareness and in the visual guidance of behavior.

Although visual input is important for spatial operations, awareness of space is more than just a visual function. It is possible to apprehend the shape of an object and know where it is, regardless of whether it is seen or sensed through touch. Accordingly, spatial awareness, considered as a general phenomenon, depends not simply on visual areas of the dorsal stream but rather on the higher order cortical areas to which they send their output. The transition from areas serving purely visual functions to those mediating generalized spatial awareness is gradual, but has been accomplished by the time the dorsal stream reaches its termination in the association cortex of the parietal lobe.

Three Spatial Processing Streams Emanate from Parietal Cortex

Numerous association areas in the cerebral hemisphere mediate cognitive functions that depend in some way on the use of spatial information originating in parietal cortex. These areas occupy a continuous region of the cerebral hemisphere, encompassing large parts of the frontal, cingulate, temporal, parahippocampal, and insular cortices. They are connected to one another anatomically and to the parietal cortex by a parallel distributed pathway through which signals shuttle back and forth (Goldman-Rakic, 1988). Within this system, there at least three systems of areas with distinguishable functions (Kravitz, Saleem,

© 2013 Elsevier Inc. All rights reserved.

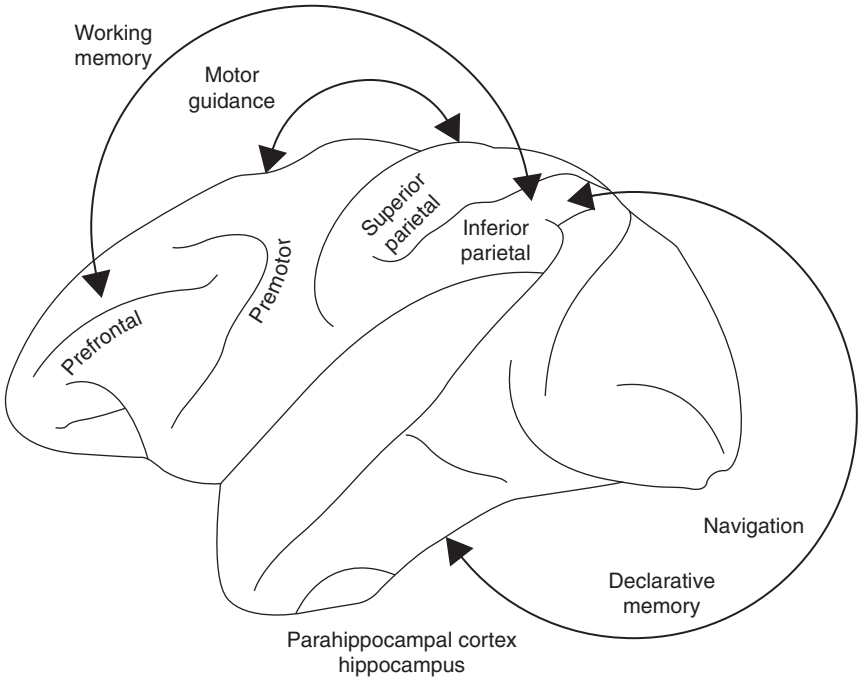

FIGURE 45.1 Lateral view of the left cerebral hemisphere of a rhesus monkey. Pathways emanating from parietal cortex link it to other cortical regions with functions that depend on spatial information. *Brain drawing, courtesy of Laboratory of Neuropsychology, NIMH.*

Baker, & Mishkin, 2011) (Fig. 45.1). The premotor areas of the frontal lobe mediate the spatial guidance of motor behavior in the workspace around the body. The dorsolateral prefrontal cortex mediates spatial functions of higher order including spatial working memory. A system of areas spanning the cingulate gyrus, the medial temporal lobe, and the hippocampus mediates the ability to navigate in the environment and spatial episodic memory. The following sections describe the spatial functions of the parietal cortex and of the far-flung system of areas to which it projects.

PARIETAL CORTEX

The Parietal Cortex Contributes to Spatial Perception and Attention

The parietal lobe is divided into superior and inferior parietal lobules. Within each lobule, several subdivisions are distinguished by anatomical and functional properties (Colby & Duhamel, 1991). In both humans and monkeys, the superior parietal lobule serves functions related primarily to somesthesis, or tactile perception, whereas the inferior parietal lobule serves functions related primarily to visuospatial cognition (Fig. 45.1). The intraparietal sulcus runs in between the superior and the inferior lobules. Within the sulcus there are several functionally distinct areas with independent representations of space. In monkeys, these include the medial intraparietal area (MIP), which is important for reaching behavior, the lateral intraparietal area (LIP), which is important for spatial attention, and the ventral intraparietal area (VIP), where visual and somatosensory representations of space are brought together. Functional imaging studies indicate that there are probably equivalent areas in humans although the detailed pattern of correspondence remains to be worked out (Grefkes & Fink, 2005).

Injury to the Human Parietal Cortex Causes Impairments of Spatial Function

The neurologist Balint in 1909 first described a group of behavioral impairments specifically associated with bilateral damage to the parietal lobe. Balint's syndrome includes difficulty in executing eye movements to engage visual targets (ocular apraxia), an inability to perceive multiple objects at the same time (simultanagnosia), and inaccuracy in reaching for visual targets (optic ataxia). Many other impairments are now known to arise from damage to parietal cortex. These include constructional apraxia, an inability to copy, through drawing or physical manipulation, the spatial pattern in which things are arranged, and hemispatial neglect, a profound unawareness of the half of space opposite the injured hemipshere. The following sections describe in detail the symptoms of optic ataxia, constructional apraxia, and neglect.

Optic Ataxia: An Impairment of Visually Guided Reaching

After damage to the parietal cortex, some patients experience difficulty in making visually guided arm movements. This condition is referred to as misreaching, or

optic ataxia (Perenin & Vighetto, 1988). Patients with optic ataxia experience difficulty in real-life situations requiring them to reach accurately under visual guidance. For example, a patient, when cooking with a frying pan, may see the handle perfectly well and yet be unable to reach accurately for it without looking directly at it (Rondot, de Recondo, & Dumas, 1977). Neuropsychologists have been able to characterize the reaching deficits of such patients in considerable detail by testing them in controlled situations.

In the test illustrated in Figure 45.2, patients were required to reach out and insert one hand into a slot in the center of a disk held by the experimenter. The disk could be held in either the right or the left visual hemifield, while the patient looked straight ahead, and the patient could be asked to reach with either the right or the left hand. To perform the task, the patient had to direct the hand toward the center of the slot and orient the hand correctly so that it would pass into it. Pictures in the top row of Figure 45.2 show a patient with right parietal lobe damage reaching with the left hand. When the disk was positioned in the right (ipsilesional) visual field, the patient was able to reach accurately (Fig. 45.2A). And yet, when the disk was in the left (contralesional) visual field, the patient committed errors of hand orientation (Fig. 45.2B) and of reaching direction (Fig. 45.2C). The lower row of Figure 45.2 shows reaching by a patient with damage to the left parietal lobe. When using the left hand in the left (ipsilesional) visual field, this patient was also able to reach accurately (Fig. 45.2D). However, when using the right hand in the right (contralesional) visual field, the patient committed errors of hand orientation (Fig. 45.2E) and of reaching direction (Fig. 45.2F).

These results demonstrate that optic ataxia may be lateralized, occurring only when the patient is required to point to targets in one visual hemifield or only when one hand is used for pointing. In cases where the deficit is restricted to a single hemifield or a single arm, the affected hemifield or arm is usually opposite the injured parietal lobe. This is expected because the parietal lobe of each hemisphere mediates communication between more posterior visual areas (which represent the contralateral half of visual space) and more anterior motor areas (which represent the contralateral arm). There are, however, cases in which the problem is bilateral or occurs for specific combinations of arm and hemifield. Optic ataxia is not simply a problem with visuospatial perception, as indicated by the fact that performance with one arm may be perfectly normal. Nor is it simply a motor problem, as indicated by the fact that patients unable to reach accurately for visual targets can commonly touch points on their own bodies accurately under proprioceptive guidance. Optic ataxia is best characterized as an inability to use visuospatial information to guide arm movements.

Constructional Apraxia: Inability to Reproduce the Spatial Relations of Parts

After injury to the parietal cortex, some patients experience difficulty in apprehending the spatial relations among elements in a scene. They cannot judge whether two objects are of the same size or which of two objects is closer. When asked to copy simple line drawings or to draw from memory, they omit or transpose parts. When attempting to reproduce with an arrangement of matchsticks a visible model in the shape of a four-pointed star, they make gross

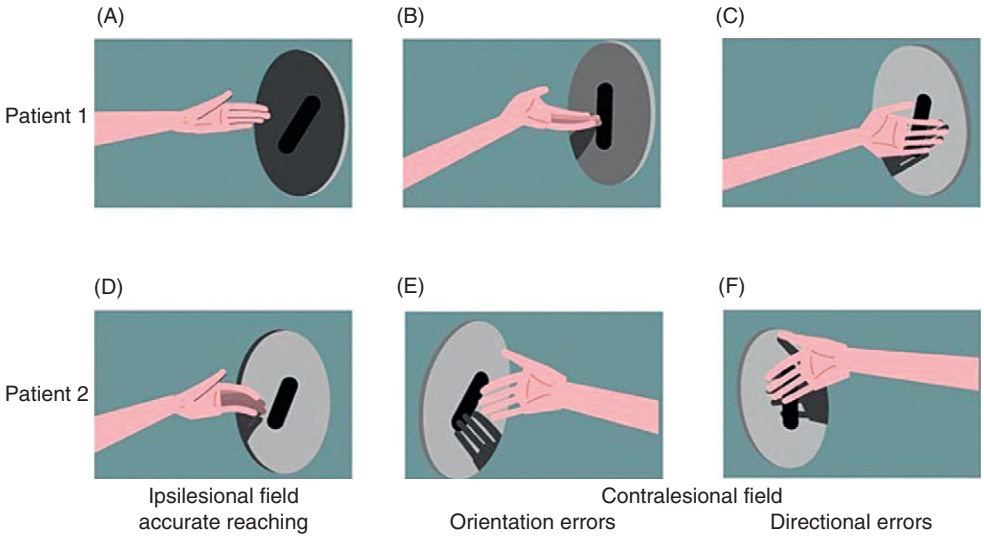

FIGURE 45.2 Optic ataxia. Patients can reach accurately (A and D) when using the ipsilesional hand in the ipsilesional visual field, but they make errors of hand orientation (B and E) and of direction (C and F) when reaching into the contralesional visual field. The top and bottom rows show the performance of two different patients. *From Perenin and Vighetto (1988).*

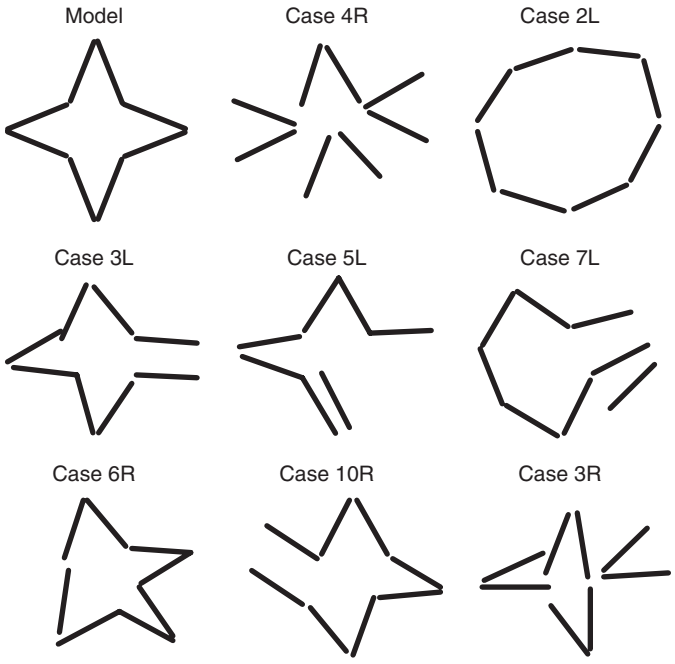

FIGURE 45.3 Constructional apraxia. Patients with parietal lobe injury make gross errors when attempting to arrange matchsticks to resemble a visible model with the shape of a four-pointed star. Cases are labeled R or L to indicate that the site of injury was in the right or left hemisphere. *From McFie and Zangwill (1960).*

errors (Fig. 45.3). The problem does not lie in a loss of fine motor control, as evidenced by the local precision with which they can arrange the matchsticks in globally incorrect configurations. The problem might arise from an inability to organize complex actions in space under visual guidance. Indeed the traditional term "apraxia" implies flawed organization of voluntary actions. It appears, however, that the difficulties arise at the stage of spatial perception rather than at the subsequent stage of motor execution. For example, in one patient with parietal-lobe injury, "difficulties of writing in print were entirely derived from his inability to locate letters and numbers on the page under visual control. Writing cursive with lowercase letters was good, since this does not require specifically visual positioning of each letter" (Vaina, 1994). Constructional apraxia, by this interpretation, is a deficit of visuospatial cognition (which depends on processing where things are relative to each other) and thereby stands in contrast to optic ataxia, a deficit of visuomotor guidance (which depends on processing where things are relative to our own bodies).

Hemispatial Neglect: Unawareness of the Contralesional Half of Space

Hemispatial neglect is a classic symptom of injury to the parietal cortex. Its key manifestation is a lateralized failure of spatial awareness. The most common form of neglect arises from damage to the right parietal lobe and is manifested as a failure to detect objects in the left half of space. Patients with neglect experience problems in daily life, such as colliding with obstacles on the contralesional side of the body or mistakenly identifying letters on the contralesional side of a written word. When asked to copy pictures or to draw simple objects from memory, they leave out details on the affected side. When asked to say whether two objects are the same or different, they tend to indicate that two dissimilar objects are the same if the differentiating details are on the contralesional side.

Neglect involves more than just a defect of attention to contralesional sensory events. For example, patients fail to report detail on the left half of an object even when they are asked to form a mental representation of the object by viewing it one part at a time as it passes slowly behind a vertical slit. In a famous set of experiments, patients were asked to imagine themselves in a familiar public setting and then to report what they would be able to see around them (Bisiach & Luzzatti, 1978). When they imagined standing at one end of the town square, patients described the buildings on the right side and failed to report buildings on the left. However, when instructed to imagine themselves standing at the other end of the square, facing in the opposite direction, they now failed to mention buildings on the left that they had described just moments before and were able to describe buildings on the right that they had previously omitted. These patients were unable to form a mental representation of the contralesional half of space even when the requirement to direct attention to sensory input on that side was altogether removed.

The fact that neglect affects the half of space opposite the injured hemisphere suggests that each parietal lobe must represent the opposite half of space. On the face of it, this proposition does not sound particularly surprising. Most visual areas in each hemisphere represent the opposite half of the visual field, most somatosensory areas represent the opposite half of the skin surface, and most motor areas represent muscles on the opposite half of the body. Injury to these areas leads to a sensory loss or motor impairment that affects the opposite half of a functional space defined with respect to some anatomical reference frame (the retina, the skin, or the muscles). In contrast, injury to the parietal cortex gives rise to a neglect that may be defined with respect to any of several spatial reference frames. These fall into two broad classes: egocentric reference frames, in which locations are represented relative to the observer, and allocentric reference frames, in which locations are represented in coordinates extrinsic to the observer. Examples of egocentric reference frames include those centered on the hand or the body. Allocentric reference frames include those centered on an environmental landmark or an object of interest. Patients with neglect often show deficits with respect to more than one reference frame. The following sections describe evidence for impairments relative to multiple spatial reference frames in neglect.

A patient with left hemispatial neglect, looking straight ahead at the center of some object, will tend not to see detail on its left side. This observation is open to several interpretations. The simplest interpretation is that stimuli presented in the left visual field tend not to be registered. However, the fundamental problem might actually be with registering stimuli that are to the left of the head, the torso or the object itself. These possibilities cannot be distinguished without disentangling the various reference frames. Experiments aimed at identifying the spatial reference frame in neglect indicate that a patient's failure to detect a stimulus is affected not only by its location relative to the retina but also by its location relative to the object or array within which it is contained, by its location relative to the body, and even by its location relative to a gravitationally defined reference frame. Patients span a continuum from exhibiting predominantly egocentric to predominantly allocentric neglect.

In many patients, a component of neglect is object centered. If these patients are presented with an image anywhere in the visual field, they tend to ignore its left side. In one experiment, patients with left hemispatial neglect were required to maintain fixation on a small spot while chimeric faces (images formed by joining at the midline half-images representing the faces of two people) were presented at various visual field locations. Their reports of what they saw were based predominantly on the right halves of the chimeric images. This was true even when the entire composite face was presented within the right visual hemifield. In a second experiment, patients with left hemifield neglect were required to maintain fixation on a small spot while four stimuli in a horizontal row were presented. One of the stimuli was a letter that was to be named aloud. When the letter was at the leftmost location within the array, patients were slowest to name it, even when the entire array was in the right visual field.

A particularly dramatic way of demonstrating the object-centered nature of neglect is to ask patients to make copies of simple line drawings (Marshall & Halligan, 1993). When asked to copy a picture of two flowers, a patient with right parietal lobe damage saw and copied each flower but omitted the petals on the left half of each, thus showing evidence of left object-centered neglect (Fig. 45.4A). When the same two flowers were joined by a common stem, the patient saw and copied the plant, but omitted details on its left side, including all of the leftmost flower, thus showing neglect for the left half of the larger composite object (Fig. 45.4B).

Patients with parietal lobe damage sometimes exhibit neglect defined with respect to allocentric reference frames other than those centered on an object. The role of a gravitational reference frame in neglect has emerged from studies in which patients face a display screen either while sitting upright or while lying on their side (Ladavas, 1987).

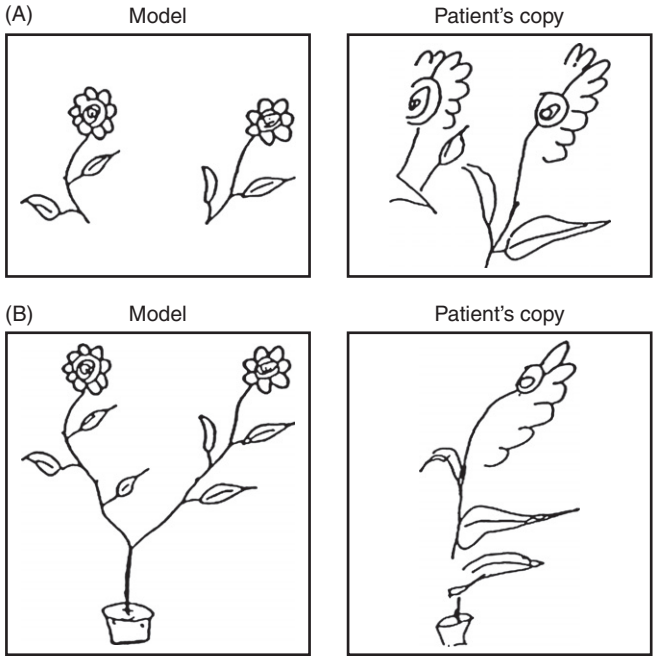

FIGURE 45.4 Object-centered neglect. When asked to copy the two drawings on the left, a patient made the two copies on the right. Detail is omitted from the left half of each object rather than from the left half of the drawing as a whole. *From Marshall and Halligan (1993).*

When the patient sits upright, the right and left halves of the screen coincide with the right and left retinal visual fields. However, when the patient lies on one side while facing the screen, the situation is changed. Reclining on the right side, the patient sees the right and left halves of the screen as being in the upper and lower visual fields, respectively. Applying this procedure to patients with left hemispatial neglect enables the investigator to pose the question: Is the neglect specific for the left retinal visual field or is it specific for the left half of the screen? Neglect turns out to depend in part on each of these factors.

Further evidence that the parietal cortex represents the locations of objects relative to an external framework comes from the observation that neglect, in some patients, is restricted to stimuli within a certain range of distances from the body. The form of neglect termed peripersonal or proximal is specific for stimuli in the immediate vicinity of the body. Another form of neglect, termed extrapersonal, is specific for more distant stimuli. The implication of these findings is that there is a localization of function within the parietal cortex and that neurons in discrete areas process sensory input from objects at different distances. Discrete areas of the parietal cortex are known to be specialized for relaying sensory information to different motor systems. Sensory input from peripersonal space is uniquely significant for guiding reaching movements. In contrast, sensory input from greater distances (extrapersonal space) is useful primarily for the control of eye movements.

Lesions of the Parietal Cortex in Monkeys Produce Spatial Impairments

The original distinction between dorsal and ventral processing streams in the primate visual system was based in part on differences in the effects of lesions of the parietal cortex, the terminus of the dorsal stream, and inferior temporal cortex, the terminus of the ventral stream (Ungerleider & Mishkin, 1982). Monkeys with parietal lesions exhibit a selective impairment of visuospatial cognition. For example, they cannot judge which of two identical objects is closer to a visual landmark. In contrast, lesions of inferior temporal cortex produce deficits in visual pattern recognition (see Chapter 44).

In addition to visuospatial cognitive deficits, monkeys with parietal lesions also exhibit deficits of visuomotor guidance. After parietal lesions, monkeys have difficulty directing eye movements toward targets in the hemispace opposite the side of the lesion (Lynch & McLaren, 1989). Further, when two targets are presented simultaneously in the ipsilesional and contralesional fields, monkeys with parietal lesions tend to ignore the contralesional stimulus, an effect termed visual extinction. Parietal lesions also interfere with the ability of a monkey to reach toward an object. Lesions confined to the inferior parietal cortex impair reaching with the contralesional limb toward a target in contralesional space. Lesions extending across the intraparietal sulcus to include the superior parietal cortex produce impairments in reaching with the contralesional arm into either half of space. In sum, monkeys with parietal lesions exhibit impairments both of visuospatial cognition and of visuomotor guidance.

Parietal Neurons Encode the Spatial Attributes of Objects and Actions

To understand more precisely how the parietal cortex contributes to spatial cognition, several groups of investigators have measured the electrical activity of single neurons during the performance of spatial tasks. These studies were carried out in alert monkeys trained to make movements to visual targets. Because brain tissue itself has no sensory receptors, microelectrodes can be introduced into the brain without disturbing the performance of an animal on a task. By recording neuronal activity during specially designed tasks, neural activity can be related directly to the sensory, cognitive, and motor processes that underlie spatial behavior. The following sections describe how neurons in specific areas within the parietal cortex are selectively activated during spatial tasks and how they contribute to spatial representation and cognition.

Area VIP: Head-Centered Visual and Somatosensory Responses

The ventral intraparietal area (area VIP) is a functionally and anatomically defined area that lies at the junction of the visual and somatosenory districts within parietal cortex. Individual neurons respond strongly to moving stimuli and are selective for both the speed and the direction of the stimulus (Colby, Duhamel, & Goldberg, 1993). In this respect, VIP neurons are similar to those in other dorsal stream visual areas that process stimulus motion, especially areas MT and MST (see Chapter 26). An important finding in area VIP is that most of these visually responsive neurons also respond to somatosensory stimuli (Duhamel, Colby, & Goldberg, 1991). These neurons are truly bimodal in the sense that they can be driven equally well by either a visual or a somatosensory stimulus. Most of these bimodal neurons have somatosensory receptive fields on the head or face that match the location of their visual receptive fields. This correspondence is illustrated in Figure 45.5, which shows visual and somatosensory receptive fields for several individual VIP neurons.

Three kinds of correspondence are found in VIP neurons. First, for each neuron, receptive fields in each modality match in location. For example, a neuron that responds to a visual stimulus in the upper left visual field also responds when the left brow is touched, and a neuron with a foveal visual receptive field also responds to cutaneous stimulation around the mouth. Second, receptive fields match in size. For example, neurons with visual receptive fields around the fovea and somatosensory receptive fields around the mouth have especially small receptive fields in both modalities. This makes sense becase the fovea and the mouth are both regions of high spatial acuity. The third type of correspondence is in the preferred directions of movement. For example, a neuron responsive to a visual stimulus moving toward the right also responds when a small probe is brushed lightly across the face of the monkey moving to the right. In sum, visual and somatosensory receptive fields for individual VIP neurons match in location, size, and directional preference.

The correspondence in receptive field locations across modalities immediately raises a question: What happens to the relative locations of the visual and somatosensory receptive fields when the eyes move? If the visual receptive field were retinotopic, it would move when the eyes do; if the somatosensory receptive field were somatotopic, it would remain in place when the eyes move. Consequently, the correspondence in location between the visual and somatosensory receptive fields would be broken by eye movements.

The answer is that visual receptive fields are linked to the skin surface and not to the retina. A neuron that

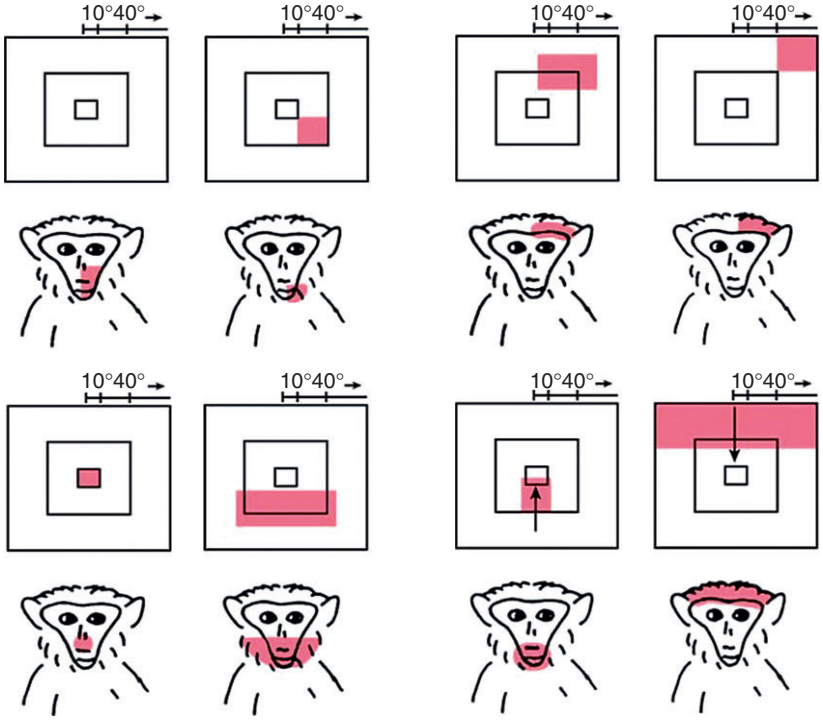

FIGURE 45.5 Matching visual and somatosensory receptive fields of neurons from area VIP. On each outline of the head of the monkey, the patch of color corresponds to the somatosensory receptive field of one neuron. On the square above the head, the patch of texture corresponds to the visual receptive field of the same neuron. The square can be thought of as a screen placed in front of the monkey so that its center was directly ahead of the monkey's eyes at the time of visual testing. *From Duhamel et al. (1991) with permission of Oxford University Press.*

responds best to a visual stimulus approaching the forehead and has a matching somatosensory receptive field on the brow will continue to respond best to a visual stimulus moving toward the brow regardless of where the monkey is looking. Thus, both visual and somatosensory receptive fields are defined with respect to the skin surface. In this sense, the receptive fields are head centered: a given VIP neuron responds to stimulation of a certain portion of the skin surface and to the visual stimulus aligned with it no matter which part of the retina the image falls on.

In sum, neurons in area VIP encode bimodal sensory information in a head-centered representation of space. This kind of representation would be most useful for guiding head movements. Anatomical studies indicate that area VIP sends information to premotor cortex including the specific region that is involved in generating head movements.

Area LIP: Retina-Centered Attentional Signals

The lateral intraparietal area (area LIP) is a functionally defined area within the visual district of parietal cortex. Neurons in LIP exhibit several different kinds of activity during spatial tasks (Colby, Duhamel, & Goldberg, 1996). First, LIP neurons, like neurons in striate and extrastriate visual cortex (see Chapter 26), respond to the onset of a visual stimulus in the receptive field of the neuron. Second, these visual responses are enhanced when the monkey attends to the stimulus: the amplitude of the visual response is increased when the stimulus or stimulus location becomes the focus of attention. This enhancement occurs no matter what kind of movement the animal will use to respond to the stimulus. Regardless of whether the task requires a hand movement or an eye movement or requires that the monkey refrain from moving toward the stimulus, the visual response of an LIP neuron becomes stronger when the stimulus is made behaviorally relevant. This means that the same physical stimulus arriving at the retina can evoke very different responses in cortex as a result of spatial attention.

A third important feature of LIP neuron activity is the sustained responses observed when the monkey must remember the location at which the stimulus appeared. In this task, a stimulus is flashed only briefly, but the neuron continues to fire for several seconds after the stimulus is gone, as though it were holding a memory trace of the target location. A particularly intriguing question in understanding spatial representation concerns the fate of this memory-related activity in area LIP following an eye movement, as will be described later. A fourth kind of activation commonly observed in LIP neurons is related to performance of a saccade—a rapid eye movement—toward the receptive field. Some LIP neurons fire just before the monkey initiates a saccade that will move the fovea onto a target presented in the receptive field. LIP neurons have overlapping sensory and motor fields, just like neurons in the superior colliculus (see Chapter 32).

Finally, LIP neuron activity can be modulated by the position of the eye in the orbit (Andersen, Bracewell, Barash, Gnadt, & Fogassi, 1990). For instance, the visual response of a given cell may become larger when the monkey is looking toward the left part of the screen than when it is looking toward the right. This property is of interest because it suggests that neurons in area LIP contribute to spatial representations that go beyond a simple replication of the retinal map.

In sum, individual LIP neurons have receptive fields at particular retinal locations; they carry visual-, memory-, and saccade-related signals; and their activity can be modulated by attention and eye position. Activity in area LIP cannot be characterized as a simple visual or motor signal. It is probably closer to the truth to think of the firing of an LIP neuron as reflecting how much attention is currently being directed to the location occupied by its receptive field.

Area LIP: Updating of Spatial Information during Eye Movements

Every time we move our eyes, each object in our surroundings activates a new set of retinal neurons. Despite this ever changing input, we experience a stable visual world. How is this possible? More than a century ago, Helmholtz proposed that the reason the world appears to stay still when we move our eyes is that the "effort of will" involved in making a saccade simultaneously adjusts our perception to take that specific eye movement into account. He suggested that when a motor command to move the eyes is issued, a copy of that command, or corollary discharge, is sent to brain areas responsible for generating our internal image of the world. This image is then updated so as to be aligned with the new visual information that will arrive in the cortex after the eye movement. A simple experiment shows that Helmholtz's account must be essentially true. When the retina is displaced by pressing on the eye, the world does seem to move, presumably because there is no corollary discharge. Without that internal knowledge of the intended eye movement, there is no way to update the spatial representation of the world around us.

Neurons in area LIP contribute to this updating of the internal image (Duhamel, Colby, & Goldberg, 1992). The experiment illustrated in Figure 45.6 shows that the memory trace of a stimulus is updated when the eyes move. The activity of a single LIP neuron was recorded under three different conditions. In the first set of trials, the monkey looked at a fixed point on the screen while a stimulus

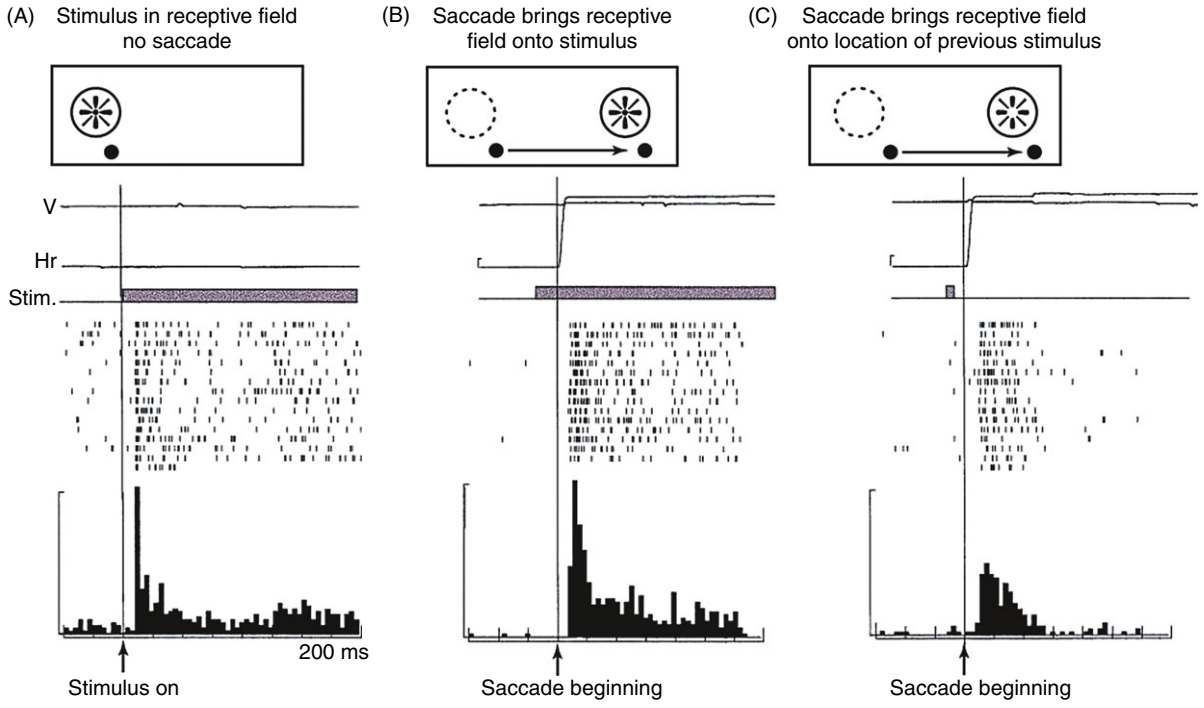

FIGURE 45.6 Remapping of visual memory trace activity in area LIP. The activity of a single neuron was recorded under three different conditions. (A) Simple visual response to a constant stimulus in the receptive field, presented while the monkey is fixating. The rasters and histogram are aligned on the time of stimulus onset. (B) Response following a saccade that brings the receptive field onto the location of a constant visual stimulus. (C) Response following a saccade that brings the receptive field onto the location where a stimulus was presented previously. The stimulus is extinguished before the saccade begins so it is never physically present in the receptive field. The neuron responds to the updated memory trace of the stimulus. V, vertical eye position; H, horizontal eye position. *From Duhamel et al. (1992).*

was presented in the receptive field (Fig. 45.6A). In the diagram at the top of Figure 45.6A, the dot is the fixation point, the dashed circle shows the location of the receptive field, and the asterisk represents the visual stimulus. The time lines just below the diagram indicate that the vertical and horizontal eye positions remained steady throughout the trial, demonstrating that the monkey maintained fixation. The stimulus time line shows that the stimulus appeared 400 ms after the beginning of the trial and continued for the entire trial. The raster display below plots the electrical activity of a single LIP neuron in 16 successive trials. In these rasters, each small dot indicates the time at which an action potential occurred, and each horizontal line of dots represents activity in a single trial. In each trial there was a brief initial burst of action potentials shortly after the stimulus appeared, followed by continuing neural activity at a lower rate. The histogram at the bottom of Figure 45.6A shows the average firing rate as a function of time. The visual response in Figure 45.6A is typical of that observed in neurons in many visual areas: the neuron fired when a stimulus appeared in its receptive field.

In the second set of trials (Fig. 45.6B), a visual response occurred when the monkey made an eye movement that brought a stimulus into the receptive field. At the beginning of the trial, the monkey looked at the fixation point on the left, and the rest of the screen was blank. Then, simultaneously, a new fixation point appeared on the right and a visual stimulus appeared above it. The monkey made a saccade from the old fixation point to the new one, indicated by the arrow. The eye movement was straight to the right so only the horizontal eye position trace shows a change. At the end of this saccade, the receptive field had been moved to the screen location containing the visual stimulus. The rasters and histogram in Figure 45.6B are aligned on the time that the saccade began. In each trial, the neuron began to respond after the receptive field had landed on the stimulus. This result is just what would be expected for neurons in any visual area with retinotopic receptive fields.

The novel finding is shown in Figure 45.6C. In this third set of trials, the monkey made a saccade that would bring a stimulus into the receptive field, just as in the second set of trials. The only difference was in the duration of the stimulus, which lasted for a mere 50 ms instead of staying on for the entire trial. As can be seen on the stimulus time line, the stimulus actually disappeared before the saccade began. This means that it was never physically present in the receptive field. Nevertheless, the neuron fired as though there were a stimulus in its receptive field. This result indicates that LIP neurons respond to the memory trace of a previous stimulus. Moreover, the representation of the memory trace is updated at the time of a saccade. The general idea of how a memory trace can be updated is as follows. At the beginning of the trial, while the monkey is looking at the initial fixation point, the onset of the stimulus activates neurons whose receptive fields encompass the stimulated location. Some of these neurons will have tonic activity and continue to respond after stimulus offset, encoding a memory of the location at which the stimulus occurred. When the monkey moves its eyes toward the new fixation point, a copy of the eye movement command is sent to parietal cortex. This corollary discharge causes the active LIP neurons to transmit their activity to a new set of neurons whose receptive fields will encompass the stimulated screen location after the saccade. By means of this transfer, LIP neurons encode the spatially updated memory trace of a previous stimulus.

The significance of this finding lies in what it illustrates about spatial representation in area LIP. It indicates that the internal image is dynamic rather than static. Tonic, memory-related activity in area LIP not only allows neurons to encode a salient location after the stimulus is gone but also allows for dynamic remapping of visual information in conjunction with eye movements. This updating of the internal visual image has specific consequences for spatial representation in the parietal cortex. Instead of spatial information being encoded in purely retinotopic coordinates, tied to the specific neurons initially activated by the stimulus, the information is encoded in eye-centered coordinates. This is a subtle distinction but a very important one in generating accurate spatial behavior. Visual information encoded in eye-centered coordinates tells the monkey not just where the stimulus was on the retina when it first appeared, but where it would be on the retina following an intervening eye movement. The result is that the monkey always has accurate information with which to program an eye movement toward a real or a remembered target. These phenomena probably occur in the human brain as well, as indicated by the observation that parietal injury can interfere with the ability to keep accurate track of a remembered location during a saccade.

In sum, neurons in area LIP encode the locations of present and remembered visual stimuli in an eye-centered reference frame. This observation suggests that area LIP is involved in eye movement control. It fits with the fact that LIP is strongly and directly connected to other brain centers involved in the control of eye movements, including the frontal eye field and superior colliculus (see Chapter 32).

Area LIP Is Downstream from Spatial Decision Processes

Spatially selective neuronal activity in area LIP is graded in strength. If the monkey's attention to a given location or intention to make a saccade in a given direction increases in strength, then the firing of LIP neurons

with response fields in that direction also increases. This has been demonstrated in decision tasks—tasks requiring the monkey to decide which of several possible saccades to make. A decision can be either sensory-based or value-based. In a sensory decision task, the monkey must judge whether a visual display contains dots moving to the right or left and must report the judgment by executing a rightward or leftward saccade (Roitman & Shadlen, 2002). If the motion stimulus is weak, requiring the monkey to integrate sensory information over time, the neuronal signal reflecting the decision develops slowly. If the motion stimulus is strong, allowing the monkey to make an instantaneous decision, the neuronal signal rises sharply. Thus, the evolution of the monkey's decision is reflected in the activity of spatially selective LIP neurons. In a value-based decision task, the monkey chooses between a saccade to the right and a saccade to the left on the basis of prior experience indicating that one of the saccades is more likely than the other to yield a valued juice reward (Sugrue, Corrado, & Newsome, 2004). During the preparatory period of the trial, LIP neurons fire strongly if the target in their response field is associated with a valuable reward. In this task the activity of spatially selective LIP neurons reflects the value of the target. These two findings do not necessarily indicate that LIP plays a direct role in making sensory or value-based decisions. They can also be explained on the assumption that LIP neurons mediate attention or motor preparation and that they fire more strongly when attention or motor preparation is more intense (Maunsell, 2004).

Summary

The parietal cortex plays a critical role in spatial awareness. Injury to the parietal cortex in humans and monkeys leads to deficits of visuomotor guidance and visuospatial cognition. Parietal neurons in monkeys construct a representation of space by combining signals from multiple sensory and motor modalities. Neurons in different divisions of parietal cortex represent locations relative to several body-centered reference frames including ones centered on the eye and head. Signals carried by these neurons are useful for visuomotor guidance. Recent studies have suggested that parietal neurons also represent locations relative to object-centered reference frames in the service of visuospatial cognition (Box 45.1).

FRONTAL CORTEX

Frontal Cortex Contributes to Voluntary Movement and the Control of Behavior

The frontal lobe is involved in spatial functions as a natural result of its being involved in behavioral control. The three main divisions of the frontal lobe are the primary motor cortex located on the precentral gyrus; the premotor cortex, located in front of the primary motor cortex; and the prefrontal cortex. The primary motor, premotor, and prefrontal areas all contribute to behavioral control, but they differ with respect to the quality of their contribution. This difference is seen in the effects of brain injury. Injury to the primary motor cortex leads to weakness and

BOX 45.1

AREA 7A NEURONS CARRY OBJECT-CENTERED SIGNALS IN A CONSTRUCTIONAL TASK

Many neurons in the monkey parietal cortex represent the locations of visual stimuli relative to parts of the body such as the eye (in area LIP) or head (in area VIP). The body-centered spatial information that they carry is potentially useful for visual guidance of actions such as looking at and reaching for things. Visuospatial cognition, however, requires understanding of where things are relative to each other rather than to the body. It is an interesting question whether monkeys are capable of visuospatial cognition and if so what neural mechanisms underlie it (Caminiti et al., 2010). This issue was clarified by a recent study indicating that monkeys indeed can perform a constructional task requiring the use of object-centered spatial information and that parietal neurons carry object-centered spatial signals during performance of the task (Chafee, Crowe, Averbeck, & Georgopoulos, 2005; Chafee, Averbeck, & Crowe, 2007). On each trial, the monkeys looked at the center of a monitor while two figures appeared in succession. First a simple block figure appeared (model in Fig. 45.7A). Then another block figure formed by removing one block from the model appeared (incomplete copy in Fig. 45.7A). Given a choice of two new blocks (choice array in Fig. 45.7A), the monkeys had to decide which one needed to be slid in horizontally to transform the incomplete copy into a duplicate of the model. On recording from parietal Area 7a, the experimenters found that neurons fired while the monkeys were looking at the incomplete copy and that their firing encoded the location of the missing part. For example, the neuron of Figure 45.7 fired more strongly when the missing part was on the left (B, D, and F) than when it was on the right (C, E, and G). They signaled the location of the missing part relative to the object, not relative to the monkey. The fact that neurons in Area 7a carry object-centered

BOX 45.1 (*cont'd*)

spatial information is consonant with connectional anatomy. Area 7a differs from other parietal areas in being connected strongly to prefrontal cortex, which serves cognitive functions, rather than to premotor cortex, which mediates visuomotor guidance. The loss of neurons with object-centered spatial selectivity might underlie symptoms of parietal injury in humans, including constructional apraxia (Fig. 45.3) and object-centered neglect (Fig. 45.4).

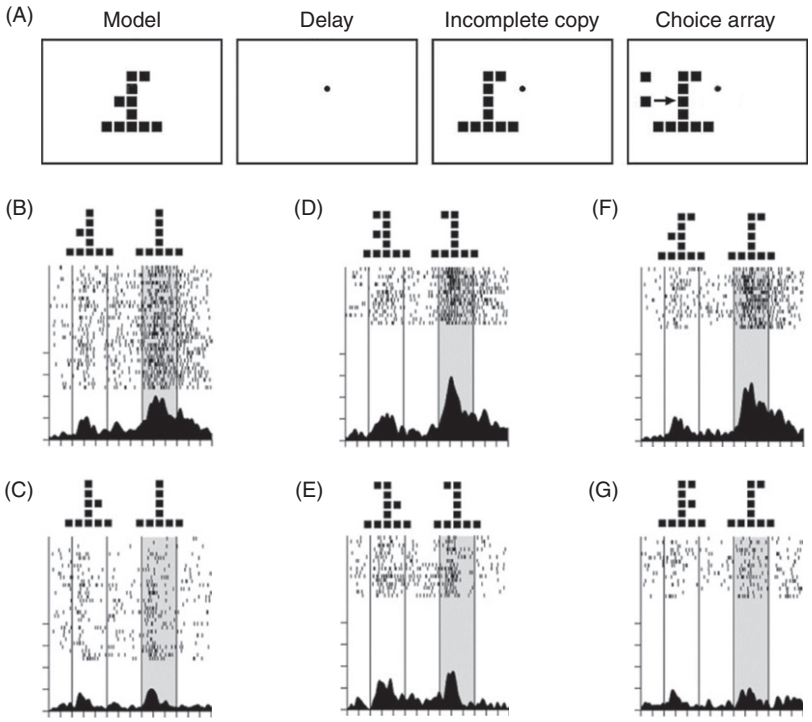

FIGURE 45.7 Data from a neuron in parietal Area 7a with object-centered spatial selectivity. (A) While the monkey looked at a fixation point at the center of the screen (the central dot in each panel), a model block figure appeared followed, after a delay, by an incomplete copy from which one block had been removed. In this example, the block protruding halfway up the model on the left side was missing. A choice array consisting of two free blocks then appeared next to the incomplete copy. The monkey had to choose which free block to slide in horizontally so as to transform the incomplete copy into the original model (arrow). In this example, the lower block was the correct choice. (B–G) Data from an Area 7a neuron. This neuron fired during the period when the monkey was viewing the incomplete model. It fired much more strongly if the missing block was on the left of the model than if it was on the right. Note that the conditions consitute matched pairs in which monkey was viewing an identical incomplete copy (B–C, D–E, and F–G). The only thing that differed between the two conditions in a pair was the monkey's awareness of the object-centered location (left or right) of the missing part. *From Chafee et al. (2005).*

paralysis of the contralateral muscles. Injury to the premotor cortex leads to difficulty in producing movements under certain circumstances—for example, when the patient is asked to mime the use of a tool or to learn arbitrary associations between stimuli and responses. Finally, injury to the prefrontal cortex results in a syndrome characterized by reduced drive, reduced ability to form and carry out plans, and an impairment of working memory (see Chapter 50). These effects indicate that progressively more anterior parts of the frontal lobe contribute to progressively more abstract aspects of behavioral control. We describe following findings from the monkey that cast light on how space is represented in primary motor, premotor, and prefrontal cortex.

Neurons of Primary Motor Cortex Represent Movement Direction Relative to Both Intrinsic and Extrinsic Frames

The primary motor cortex contains a map of the muscles of the body in which the leg is represented medially, the head laterally, and other body parts at intermediate locations. Within this map are patches of neurons that represent different muscles. Neurons within a given patch receive proprioceptive input from a muscle or small group of synergistic muscles and send their output back to that muscle or group of synergists by way of a multisynaptic pathway through the brainstem and spinal cord. There have been many studies in which the electrical activity of

neurons in the primary motor cortex is monitored while animals move (see Chapter 29). The general conclusion of these studies is that neurons in the primary motor cortex are active when the corresponding muscles are undergoing active contraction. Neurons in the primary motor cortex probably do more, however, than simply encode the levels of activation of individual muscles. One proposal is that they encode movement trajectories. Every voluntary movement can be described in two quite different but perfectly complementary ways: in terms of the lengths of the muscles or in terms of the position of the part of the body being moved. For example, during an arm movement, changes take place both in the lengths of muscles acting on the arm and in the position of the hand. Could it be that neurons in the primary motor cortex encode an extrinsic variable, such as the direction of movement of the hand, rather than an intrinsic variable such as which muscles are contracting?

Evidence for the idea that some neurons of the primary motor cortex encode movement direction relative to an extrinsic frame has come from studies in which monkeys make reaching movements in various directions. Individual neurons are selective for a specific direction of movement: a given neuron may fire most strongly during movements up and to the right and progressively less strongly for movements that deviate from the preferred direction (Schwartz, Kettner, & Georgopoulos, 1988). The patterns of selectivity are well defined, and the preferred directions of different neurons cover the range of possible movements fairly evenly. By recording the activity of the entire population of neurons one could, in principle, quite accurately describe the movement. The question remains whether these neurons are selective for the direction of movement in space or for the specific patterns of muscle activation associated with particular movements. In an elegant study, Kakei, Hoffman, and Strick (1999) recorded from neurons in the primary motor cortex while the monkey moved its hand in a single direction using different combinations of muscles. They discovered that the primary motor cortex contains both neurons selective for movement direction and neurons selective for patterns of muscle activation.

Premotor Neurons Resemble Parietal Neurons in their Patterns of Spatial Selectivity

One of the general functions of premotor cortex is to act as a conduit through which signals generated in parietal cortex control motor output. Connections between parietal and premotor cortex are organized topographically with the result that each functionally distinct subregion of parietal cortex projects particularly strongly to a related region in premotor cortex (Rizzolatti & Lupino, 2001). Premotor neurons are thought to have a more direct involvement in voluntary motor control than parietal neurons. However, they appear to preserve parietal codes for representing the locations of targets and the directions of movements. Thus, the functional properties of neurons in each region of premotor cortex mirror the functional properties of neurons in the related parietal region. For example, neurons in the division of ventral premotor cortex (PMv) linked to parietal area VIP respond both to visual and to somatosensory stimuli and possess head-centered receptive fields (Fogassi et al., 1992). Likewise, neurons in the frontal eye field (FEF), which is linked to Area LIP, possess retina-centered visual receptive fields and exhibit remapping in conjunction with eye movements (Umeno & Goldberg, 1997).

Neurons in the Supplementary Eye Field Encode the Object-Centered Direction of Eye Movements

A particularly interesting form of allocentric spatial representation analogous to that observed in area 7a (Box 45.1) has been observed in the supplementary eye field (SEF). The SEF is a division of the premotor cortex with attentional and oculomotor functions. Neurons in this area fire before and during the execution of saccadic eye movements. Several characteristics of the SEF set it apart from subcortical oculomotor centers and suggest that its contribution to eye movement control occurs at a comparatively abstract level. For example, neurons here fire while the monkey is waiting to make an eye movement in the preferred direction, as well as during the eye movement itself. Moreover, some SEF neurons become especially active when the monkey is learning to associate arbitrary visual cues with particular directions of eye movements.

In monkeys trained to make eye movements to particular locations on an object, SEF neurons encode the direction of the impending eye movement as defined relative to an object-centered reference frame (Olson & Gettner, 1995). Regardless of where an object appears relative to the body, these neurons respond when the animal is planning to make an eye movement to a specific location on that object. An experiment demonstrating this point is shown in Figure 45.8. This figure shows the activity of a single SEF neuron while the monkey performed an eye movement task. At the beginning of each trial, the monkey fixated a dot at the center of a screen. While the monkey fixated, a sample and cue were presented in the right visual field. The cue flashed on either the right or the left end of the short horizontal sample bar. Following extinction of the sample–cue display, the monkey maintained fixation for a brief time. Then, simultaneously, the central spot was extinguished and a target bar appeared at an unpredictable location in the upper visual field of the monkey. The monkey had to make an eye movement to the end of the target bar corresponding to the cued end

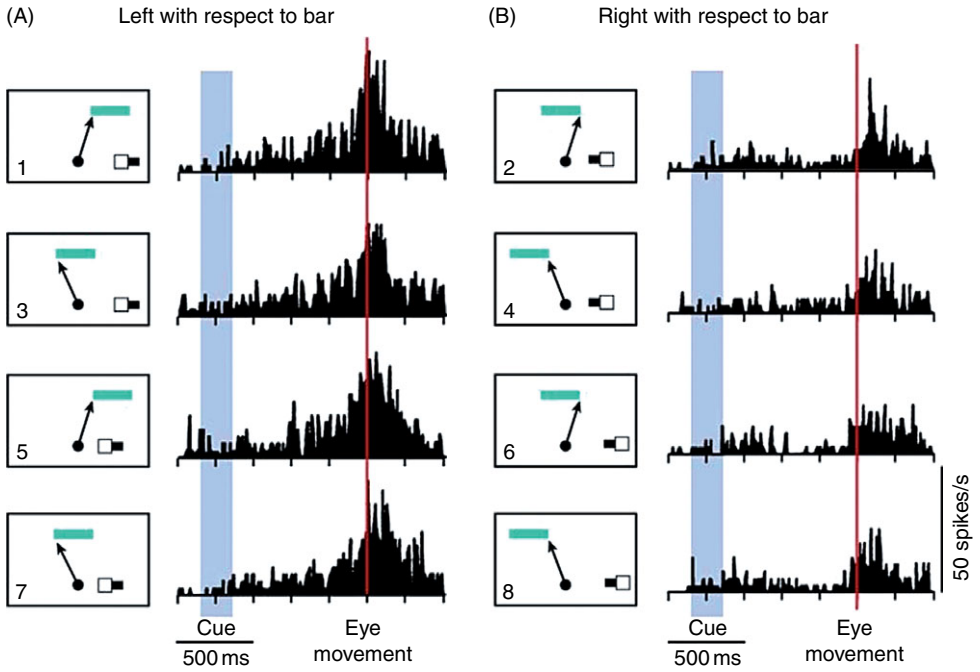

FIGURE 45.8 Data from a neuron in the SEF selective for the object-centered direction of eye movements. The monkey was trained to make eye movements to the right or left end of a horizontal bar. A cue appeared on the small sample bar shown in the lower right of each panel (1–8) to tell the monkey which end of the target bar (top in each panel) was relevant on a given trial. The arrow in the panel next to each histogram indicates the direction of the eye movement. The neuron fired strongly when the eye movement was directed to the left end of the target bar (left column) regardless of whether the physical movement of the eye was up and to the right (panels 1 and 5) or up and to the left (panels 3 and 7). *From Olson and Gettner (1995).*

of the sample bar. Across the set of eight conditions, the object-centered direction of the eye movement was completely independent of its physical direction.

This situation made it possible to ask whether the activity of the neuron was related to the object-centered direction of the movement or to its physical direction. To the right of each panel in Figure 45.8 is shown the average firing rate of a single neuron as a function of time during the trial. Regardless of the direction of the physical movement of the eye, firing was clearly stronger on trials in which the monkey made an eye movement to the left end of the target bar than on trials in which the target was the right end of the bar. For example, in panels 1 and 2, the physical direction of the eye movement was exactly the same, and yet firing was much stronger when the left end of the bar was the target (panel 1) than when the right end of the bar was the target (panel 2). This neuron exhibited object-centered direction selectivity in the sense that it fired most strongly before and during movements to a certain location on an object.

Object-centered direction selectivity serves an important function in natural settings. In scanning the environment, we sometimes look toward locations where things are expected to appear, but which, at the time, contain no detail, for example, the center of a blank screen or the center of an empty doorway. Our eyes are guided to these featureless locations by surrounding features that define them indirectly. It is specifically in these cases that the SEF may contribute to the selection of the target for an eye movement.

The Prefrontal Cortex Mediates Working Memory for Spatial Information

Working memory is required to hold a plan in mind and carry it out step by step (see Chapter 50). The fact that this ability is severely impaired in some patients following prefrontal injury indicates that prefrontal cortex plays a crucial role in working memory. Insofar as plans and working memory have a spatial component, operations carried out by the prefrontal cortex are also spatial in nature. Single neuron-recording experiments in monkeys performing delayed-response tasks have demonstrated the importance of the dorsolateral prefrontal cortex for both spatial and nonspatial forms of working memory (Funahashi, Bruce, & Goldman-Rakic, 1991). A delayed-response task consists of several trials, each several seconds long. At the beginning of each trial, a cue is presented briefly, instructing the monkey which response to make, but the reponse must be withheld until the end of the trial. Delayed-response tasks can be designed so that both the cues (for example, spots flashed to the right or left of fixation) and the responses (for example, eye movements to the right or left) are spatial. In the context of these spatial

tasks, prefrontal neurons are active during the period between the cue and the signal to respond, when the monkey is holding spatial information in working memory. The simple interpretation of this pattern of activity is that it is a neural correlate of the monkey actively remembering the cue and holding in mind the intended response. This interpretation is consistent with results from brain imaging studies demonstrating prefrontal activation in humans performing working memory tasks.

The idea that the prefrontal cortex mediates spatial working memory has received further support from lesion experiments in monkeys. After injury to or inactivation of specific locations in the prefrontal cortex, monkeys are impaired at remembering locations in the opposite half of space. Their delayed responses are spatially inaccurate and the inaccuracy is exacerbated by making delays longer. An experiment demonstrating the importance of the prefrontal cortex for spatial working memory is illustrated in Figure 45.9, which shows behavioral data from a monkey trained to perform an oculomotor delayed-response task (Sawaguchi & Goldman-Rakic, 1994). At the beginning of each trial, the monkey fixated a spot at the center of the screen. While the monkey maintained fixation, a cue was flashed at one of six possible locations.

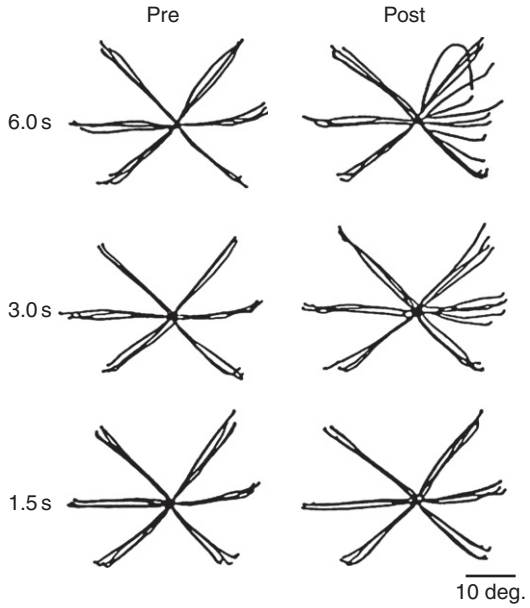

FIGURE 45.9 Inactivation of the left prefrontal cortex disrupts spatial working memory in the right half of space. A monkey was trained to fixate a central spot while a peripheral cue was presented briefly at one of six locations. After an interval of 6, 3, or 1.5 seconds, the fixation spot was extinguished and the monkey made an eye movement to the remembered location. Each set of diverging rays shows the trajectories of eye movements executed under a certain set of conditions. The left column shows eye movement performance before inactivation by a dopamine antagonist. The right column shows performance after inactivation. When the cue was in the right hemifield and the monkey was required to remember its location over long delays, the movements became highly inaccurate. *From Sawaguchi and Goldman-Rakic (1994).*

Following presentation of the cue, a delay of 1.5 to 6 seconds ensued before the monkey was permitted to make an eye movement to the cued location. Data from a normal monkey are shown in the left column of Figure 45.9. In each panel, the six bundles of radiating rays represent the eye trajectories on trials when the cue was at the six different locations. Even when required to remember the cue for 6 seconds, the monkey made accurate eye movements. Data in the right column are from the same monkey after a dopamine antagonist was injected into the left prefrontal cortex. The ability of the monkey to remember the location of the cue remained intact when the cue was in the left (ipsilesional) visual field, as shown by the accurate eye movements. However, performance deteriorated on trials when the cue was in the right (contralesional) visual field. Especially after long delays (top panel), the direction of the eye movement began to deviate from the location of the cue, as if the working memory of the monkey were fading. The fact that this deficit was specific to long delays is noteworthy because it rules out any simple explanation based on interference with visual or motor processes as opposed to working memory itself.

Neural signals related to working memory are observed in object memory tasks as well as spatial tasks (see Chapter 50). In a task in which the monkey had to remember the identity of an object as well as its location, some neurons were selectively activated by remembering the identity of the object independently of its location (Rao, Rainer, & Miller, 1997). Thus, the functions of prefrontal cortex include but are not limited to spatial cognition.

Value Representation and Motivational Modulation in Frontal Cortex

In many areas of the frontal lobe, neurons fire more strongly when a monkey anticipates receiving a larger reward for making a saccade (Roesch & Olson, 2003). The firing of these neurons could signify either of two things. First, it might represent, in an economically meaningful sense, the value of the reward that the monkey expects to receive. The monkey might commit more or less firmly to making the saccade on the basis of how strongly the neurons are firing. Second, it might simply be related to motor planning, attention, or arousal—internal states enhanced when the monkey is more motivated. That these interpretations are different can be illustrated by a simple example. The neck muscles of some monkeys grow more tense when they are planning a saccade in expectation of getting a larger reward (Roesch & Olson, 2004). The tension of the neck muscles obviously reflects motivation and does not represent value in an economically meaningful sense. Whether the activity of frontal neurons represents value or reflects motivation cannot be determined by experiments manipulating solely the size of the expected reward because, as value increases, so does motivation.

This issue has been resolved by manipulating independently the size of the reward promised in the event of the monkey's successfully completing the trial (one or three drops of juice) and the size of the penalty threatened in the event of failure (a one-second or eight-second time-out). A large promised reward and a large threatened penalty have opposite value but both act to increase motivation. Spatially selective neurons in premotor cortex fire more strongly when either a large reward has been promised or a large penalty has been threatened (Fig.

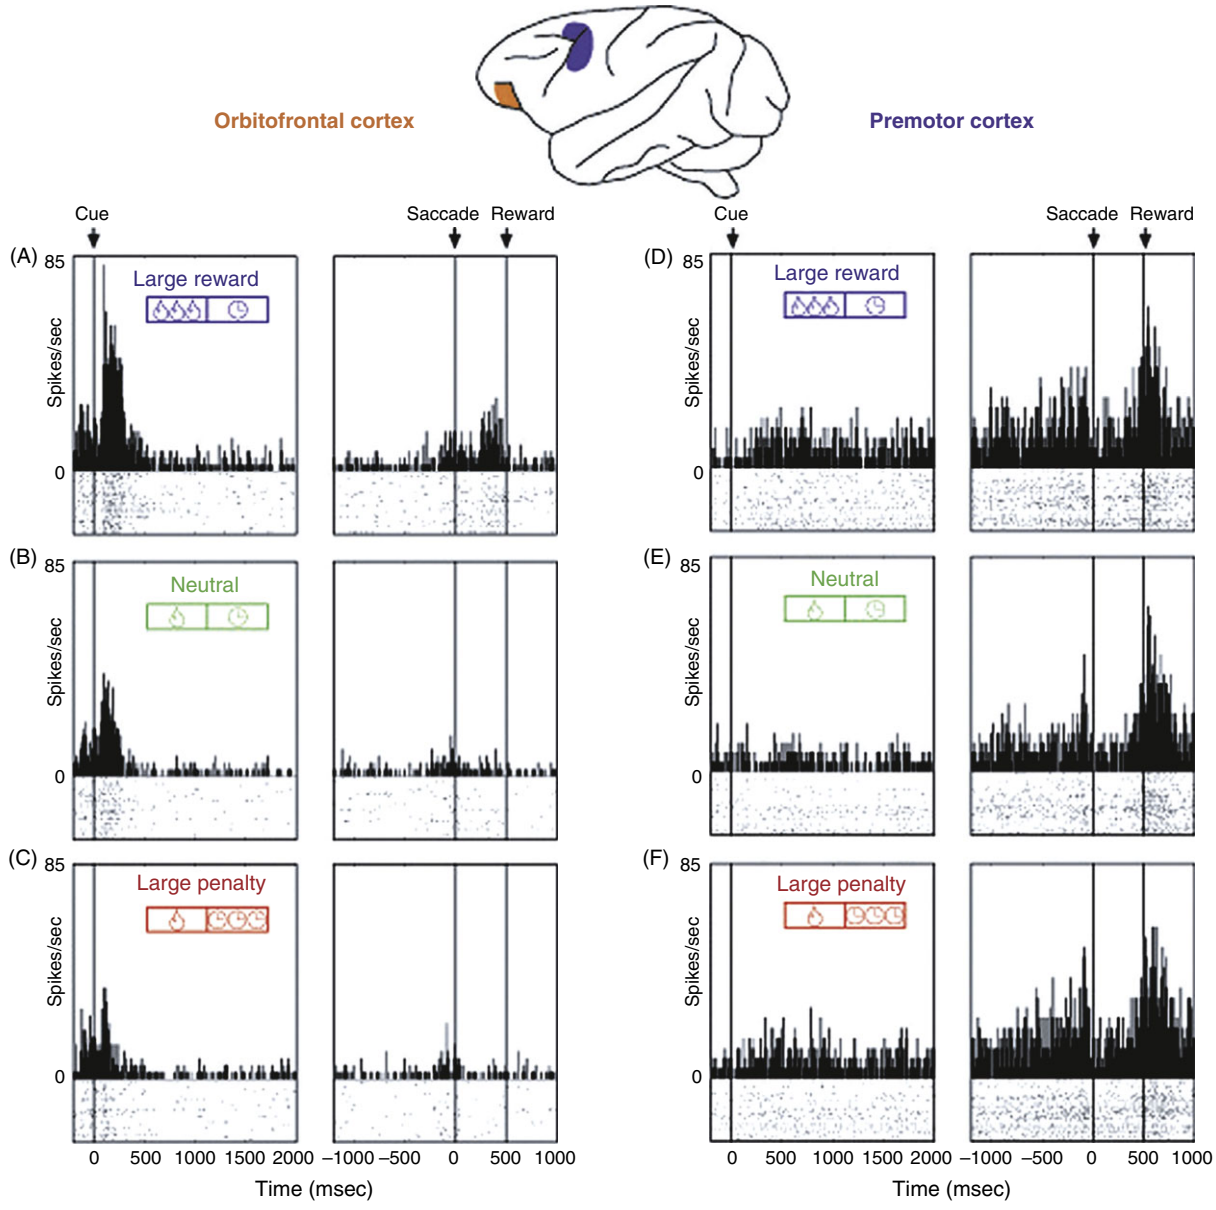

FIGURE 45.10 Evidence that orbitofrontal neurons encode expected value whereas premotor neurons are subject to motivational modulation. A cue presented early in each trial instructed the monkey whether to make a rightward or leftward saccade at the trial's end. It also indicated whether making the instructed saccade would lead to a large or small reward (three drops or one drop of juice). Finally, it indicated whether failure to make the saccade would lead to a large or small penalty (a 1-second or 8-second time-out). After a delay of several seconds, the monkey was permitted to respond. For a saccade in the instructed direction, the monkey received the promised reward. For any other response, the monkey incurred the threatened penalty. The orbitofrontal neuron encoded the value of the outcomes predicted by the cue. It responded most strongly when the combined predicted outcome was best (A: large reward promised and small penalty threatened), at an intermediate level when it was middling (B: small reward promised and small penalty threatened) and least strongly when it was worst (C: small reward promised and large penalty threatened). The premotor neuron fired during the delay period at a rate that reflected how motivated the monkey was. It fired most strongly when the monkey had something significant to work for, either earning a large reward (D) or avoiding a large penalty (F) and least strongly when little was at stake (E). In each panel, time is on the horizontal axis. The histogram represents the average firing rate of the neuron as a function of time during the trial. In the underlying raster display, each horizontal line corresponds to a single trial and each dot represents an action potential. *From Roesch and Olson (2004).*

45.10). In other words, activity in these neurons is modulated by the animal's level of motivation. In contrast, neurons in orbitofrontal cortex fire most strongly when a large reward has been promised and least strongly when a large penalty has been threatened. In other words, they represent anticipated value. The orbitofrontal cortex is a part of the limbic system known to be involved in emotional processes. Presumably, when the monkey considers an action that would lead to an outcome, neurons in orbitofrontal cortex signal the emotion that would be elicited by the outcome, thus representing its value. Value representations in orbitofrontal cortex may give rise to motivational modulation in premotor cortex.

Summary

Neurons in the frontal cortex represent spatial information in conjunction with the role they play in controlling spatially organized behavior. Neurons in the primary motor cortex encode the directions of movements. Neurons in the premotor cortex encode locations relative to numerous body-centered reference frames. SEF neurons encode locations in an allocentric, object-centered representation. Neurons in the prefrontal cortex encode the locations of and identity of objects being held in short-term memory. The motor and cognitive spatial signals carried by neurons in the frontal cortex are subject to motivational modulation.

MEDIAL TEMPORAL LOBE

The Hippocampal System Mediates Declarative Spatial Memory

The hippocampus is an area of primitive cortex, or allocortex, hidden within the medial temporal lobe. It is connected to a set of immediately adjacent temporal-lobe areas, including the perirhinal, entorhinal, and parahippocampal cortices (Zola-Morgan & Squire, 1993). The hippocampal system plays a critical role in the formation of declarative memories in humans (see Chapter 48). Consequently, patients with damage to the hippocampal system sometimes exhibit quite dramatic impairments of spatial memory as manifest in navigational behavior. The noted patient H.M., for example, experienced profound difficulty in learning to navigate through a new neighborhood. Likewise, patient E.P., profoundly amnesic after extensive medial temporal damage resulting from a viral encephalitis, could not learn the layout of a new neighborhood (Teng & Squire, 1999). The deficit in these cases concerned the formation of declarative memories in general rather than some specifically spatial function. Navigation, in itself, was intact, as evidenced by good performance in neighborhoods familiar from before the injury. Moreover, the amnesia extended to non-spatial material, as evidenced by behavior such as failing to recognize examiners to whom the patients had been introduced only minutes before.

Parahippocampal and Retrosplenial Cortex Contribute to Navigation

The retrosplenial and parahippocampal areas are located in the medial temporal lobe close to the hippocampus. They are linked by multisynaptic pathways both to parietal cortex and to the hippocampus. Thus, they are strategically positioned to mediate navigational ability, which depends on both spatial information processing and memory. Studies in humans, based on functional imaging and on the analysis of the behavioral effects of lesions, indicate that these areas may indeed play a special role in environmental navigation (Epstein, 2008). The parahippocampal place area (PPA) and the retrosplenial cortex (RSC) respond with stronger functional activation to images of scenes than to images of faces or objects (see Chapter 44). Moreover, damage to the region of the medial temporal lobe within which they reside leads to topographic disorientation (Barash, 1998). In one form of topographic disorientation, thought to arise from damage to the PPA, individuals become lost because they cannot recognize places that should be familiar (Epstein, 2008). In another form of the disorder, thought to arise from damage to the RSC, individuals are able to recognize familiar places but are unable to orient from the familiar place to a distant destination (Epstein, 2008).

Neurons in the Rat Hippocampal System Encode Place and Heading

Recordings from hippocampal neurons in rats running mazes or exploring open areas have revealed a remarkable degree of spatial selectivity. Many neurons in the hippocampus have place fields: a given neuron will fire most strongly when the rat is within a certain sector of the environment. Different neurons have distinct place fields so that, collectively, they cover the environment (Fig. 45.11B). Place fields are defined relative to prominent environmental landmarks. When a radially symmetric eight-arm maze is rotated relative to a surrounding room containing salient landmarks the place fields remain fixed with respect to the room. Even in darkness, neurons continue to fire when the rat is in their place field, indicating that these responses are not simply visual. If the rat is placed in a new environment, hippocampal neurons develop new place fields rapidly. The location of the place field of a neuron in the new environment is generally unrelated to its location in the old environment. Thus, the hippocampus develops an entirely new place-field map for

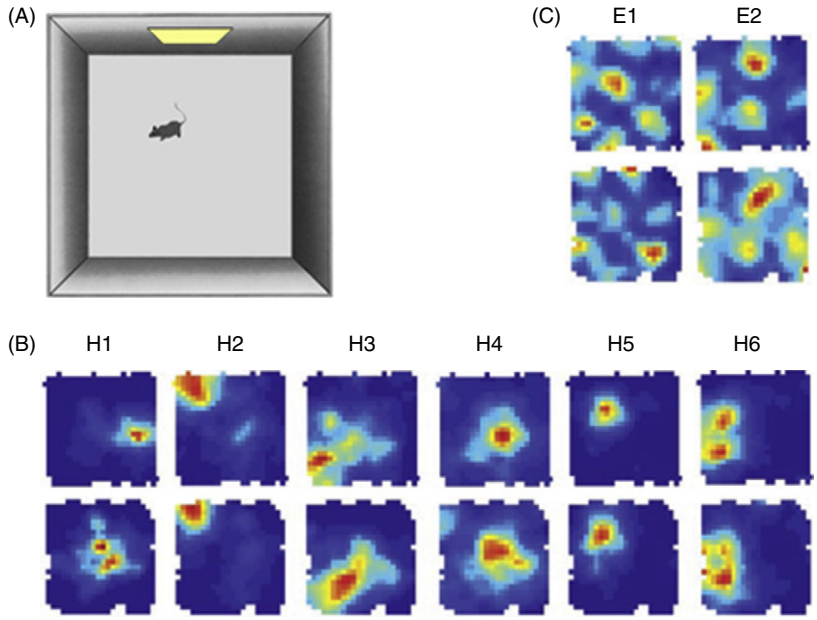

FIGURE 45.11 Neurons in the hippocampal system fire differentially as a function of a rat's location in the environment. (A) In this experiment, the rat moved freely through a square enclosure with low walls in which a card placed on one wall formed a visible landmark. (B) Data from six hippocampal neurons (H1 through H6) with place fields. Each heat map depicts the rate of firing of the neuron as a function of the rat's location in the enclosure (red indicates strong activity and dark blue indicates weak activity). The top row and the bottom row, representing data from separate sessions, are included to indicate the reproducibility of environmental spatial selectivity. (C) Data from two entorhinal grid cells (E1 and E2). Conventions as in (B). Note that each grid cell has multiple sub-fields within the enclosure. *From Fyhn, Molden, Witter, Moser, and Moser (2004).*

each new environment. This is true even in cases where the workspace is changed without any change in the surrounding room—for example, through replacement of an eight-arm radial maze by an open field.

Neurons in other regions of the hippocampal system are sensitive to the direction in which the head is pointing. Sensitivity to heading is common in the postsubiculum, a cortical area adjacent to and closely linked to the hippocampus. Each postsubicular neuron fires most strongly when the head of the rat is pointing in its preferred direction and fires progressively less strongly as the orientation of the head of the rat deviates farther from that direction. In a room that is suddenly darkened, postsubicular neurons remain sensitive to the heading of the rat so long as the rat retains a sense of spatial orientation. When the sense of spatial orientation drifts away from veridicality during prolonged darkness, as evidenced by the occurrence of systematic errors on spatial tests, then the preferred headings of postsubicular neurons exhibit a commensurate drift. These observations establish that neurons of the hippocampal system are sensitive to the rat's perceived heading.

Within limits, rats are able to maintain an accurate sense of place while they move through a dark environment. We know that they can do so both because they are able to find familiar locations and because the firing of their place cells is appropriately updated as they move. The updating of place cell activity depends on an underlying computation often termed path integration. In path integration, the rat's old location and the rat's own movement are added together to give the rat's new location. The computation is easy to describe but the neural machinery mediating it has not been understood. Recent evidence from single-neuron recording studies of the entorhinal cortex has suggested a solution to this problem. The entorhinal cortex, a source of strong and direct input to the hippocampus, contains grid cells (Hafting, Fyhn, Molden, Moser, & Moser, 2005; Moser, Kropff, & Moser, 2008). In contrast to a hippocampal place cell, which possesses a single place field in any given environment, an entorhinal grid cell possesses a multitude of firing fields covering the environment in a strikingly regular hexagonal grid (Fig. 45.11C). The firing fields of different grid cells cover the environment at a variety of scales and phases so that for each location in the environment there is a unique pattern of activity across the population of grid cells. Thus, grid cells in the entorhinal cortex encode information about the rat's current location and could relay this information to place cells in the hippocampus. The question remains: why should place information be represented in such a complex code at the level of entorhinal cortex? Soon after the discovery of grid cells, computational neuroscientists realized that representing environmental locations in a grid code could facilitate the computations that underlie path integration. Path integration has now been implemented in several models of the hippocampal system that incorporate grid cells (Fuhs & Touretzky, 2006; McNaughton, Bataglia, Jensen, Moser, & Moser, 2006).

Summary

The hippocampal system mediates the formation of declarative memories, including memories with spatial content. Injury to the hippocampal system induces a profound anterograde amnesia manifest in the spatial domain as an amnesia for neighborhood layout. In addition to mediating domain-general memory processes, the medial

temporal lobe may make specific contributions to navigation in the environment. In humans, the parahippocampal and retrosplenial cortices contribute to recognizing familiar places and orienting from them to distant goals. In the rat hippocampal system, the existence of place cells, head-direction cells, and grid cells argues for a specific and dedicated role in maintaining and updating a representation of the animal's location and heading in the environment.

SPATIAL COGNITION AND SPATIAL ACTION

The preceding sections described how spatial information is processed in cortical areas that serve distinct functions, such as motor control, attention, working memory, declarative memory, and navigation. Even within the motor system, there appears to be a fractionation of spatial functions in that neurons controlling movements of the eyes, head, and arm represent the locations of visible targets relative to eye-, head-, and hand-centered reference frames, respectively. In addition to these distinctions, there may be another fundamental distinction within brain systems mediating spatial functions. Areas mediating conscious awareness of spatial information may be partially separate from those mediating the spatial guidance of motor behavior. These functions might seem inseparable insofar as one must be aware of the location of a thing in order to look at it or reach for it. However, this is not necessarily the case. An indication that spatial awareness and spatially programmed behavior are distinguishable has come from studies of patients with "blindsight" (Weiskrantz, 1996). This condition arises as a result of injury to the primary visual cortex. Patients experience a scotoma, an area of blindness, in the part of the visual field represented by the injured cortex. The blindness is total in the sense that patients do not report seeing visual stimuli when stimuli are presented within the confines of the scotoma. Nevertheless, if patients are asked to look toward or to reach for an unseen stimulus, choosing the target by guesswork, their responses are directed to the correct location.

Similar findings have been reported in patients with diffuse pathology affecting widespread areas, including the prestriate visual cortex. One such patient, D.F., has been extensively studied in spatial tasks (Goodale et al., 1994). The results reveal an important distinction between spatial performance and spatial cognition. When asked to express spatial judgments (for example, to indicate the size of a visible object by spreading the thumb and forefinger), D.F. performs poorly. Nevertheless, when asked to make visually guided movements (for example, to reach for an object), she accurately adjusts her grip size and hand orientation under visual control to grasp the object efficiently. The fact that intact visuomotor performance coexists with profoundly impaired visuospatial perception in some patients seems to argue for the existence of distinct brain systems specialized for conscious spatial awareness and motor guidance. Many lines of evidence indicate that conscious spatial awareness depends on relatively lateral regions of parietal cortex while motor guidance depends on more medial regions of parietal cortex. Conscious spatial vision is distinct from conscious visual recognition, which depends on occipitotemporal cortex (see Chapter 44).

Summary

Spatial cognition is a function of many brain areas. No one area is uniquely responsible for the ability to carry out spatial tasks. Nevertheless, some generalizations can be made about the part of the problem that is solved in each brain region. The parietal lobe plays a crucial role in many aspects of spatial awareness. It contains numerous areas within each of which neurons carry spatial information relevant to a particular form of behavior.

Neural pathways emanating from parietal cortex relay spatial information to at least three cortical systems that elaborate it for specific purposes. The pathway to premotor cortex is critical for spatial guidance of actions in the workspace surrounding the body. The pathway to prefrontal cortex is critical for cognitive functions including spatial working memory. The pathway to the medial temporal lobe is critical for spatial declarative memory and for navigational ability.

Beneath the seeming unity of spatial experience lies a diversity of specific neural representations. The brain constructs not one but many internal representations of space. A challenge for the future is to understand how these many representations are bound up into that single seamless awareness of space with which each of us is familiar.

CHAPTER

46

Attention

INTRODUCTION

Intuition, together with cognitive and psychophysical experiments, shows that the brain is limited in the amount of information it can process at any moment in time. For instance, when people are asked to identify the objects of a briefly presented scene, they become less accurate as the number of objects increases. Similarly, when people concentrate on one demanding task (e.g., mental arithmetic) this typically comes at the expense of performance on other simultaneous activities (e.g., recalling a familiar tune). Limitations on the ability to simultaneously carry out multiple cognitive or perceptual tasks reflect the limited capacity of some stage or stages of sensory processing, decision making, or behavioral control. As a result of such computational bottlenecks, it is necessary to have neural mechanisms in place to ensure the selection of stimuli, or tasks, that are immediately relevant to behavior. "Attention" is a broad term denoting the mechanisms that mediate this selection.

In his *Principles of Psychology* published in 1890, William James wrote, "Everyone knows what attention is. It is the taking possession by the mind in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought.... " In modern neuroscience—specifically, neurophysiological research with animals—attention is defined with respect to the external world, as the focusing on one of many possible sensory stimuli. Despite their apparent discrepancies, these definitions have two features in common. They highlight the selective character of attention and highlight the cognitive nature of this selection: the fact that, whether directed without or within, attention guides selection of stimuli or thoughts.

Over the past several decades, research has concentrated on the relation between attention and sensory perception. Clearly, it is possible to focus on selected stimuli in any sensory modality—sights, sounds, smells, and touch. Most studies, however, have examined vision, the dominant sensory modality for humans and nonhuman primates. These experiments have investigated visual attention at multiple levels, ranging from behavior to the single neuron. This chapter outlines the view of attention that has emerged from these studies. A key observation is that attending to an object enhances the influence of that object over behavior and the extent to which it can be accurately perceived and reported. Conversely, withdrawing attention, either by force of the behavioral context or following certain brain lesions, can render observers practically blind to visual events. A second key point is that the attentional processes that underlie perceptual selection may also guide the voluntary eye movements with which foveate animals, such as monkeys and humans, scan the environment. A final point is that attention is closely coordinated with an ongoing task, gathering information that serves the current actions. In terms of neural organization, although some neural centers have been closely linked with the control of attention, attention appears to affect the activity of neurons at almost all levels of the visual system.

DEFINITIONS AND VARIETIES OF ATTENTION

Empirical studies have generally adopted two operational definitions of attention. Some studies, heralding back to early studies of Pavlovian learning, define an attended stimulus as one that preferentially controls behavior. Other, psychophysically based studies adopt a narrower definition, whereby an attended stimulus is one whose discriminability or detectability is modified (typically increased) during performance of a task. In general, these two definitions are well-aligned with each other. Consider for example coming to a busy intersection and

© 2013 Elsevier Inc. All rights reserved.

examining the traffic light before deciding what to do next. By the first definition we would say the light is attended since it controls one's future action (stop or proceed). By the second definition we would also say the light was attended, since the subject will be able to report the color of the light. We note, however, that while the equivalence of action-based and perception-based attention has been assumed in the field, the mechanisms of these processes may not be identical and are under active investigation.

Just as they have the capacity to flexibly link attention to action, individuals have great flexibility as to how, why, and to what precisely they attend. Attending to an object often is accompanied by overt orienting toward that object using the eyes and possibly also the head and body. When a person enters a room, it is natural to turn in that person's direction. However, one can also attend covertly to objects without looking directly at them. When driving, one can monitor a passing car while continuing to look straight ahead. Covert attention can improve peripheral visual acuity, thereby extending the functional field of view. Although one can direct attention without moving the eyes, the converse does not appear to be true: experiments show that covert attention must be deployed to an object before that object can be targeted with an eye movement. Indeed, saccades—rapid eye movements used most commonly for scanning the environment—may be considered a motor manifestation of visual attention, a relationship that is discussed in more detail later.

Certain external stimuli can summon attention in and of themselves. These can be physically salient objects, such as especially large, bright, or loud objects, or stimuli with special learned significance, such as one's own name or a mother's face. This mode of attentional engagement, known as *exogenous* or *stimulus driven*, ensures that salient and potentially important external events do not pass unnoticed even if they are not being actively sought out. However, purposeful behavior often requires that attention be directed voluntarily, or *endogenously*, based on internally defined goals and against potential external distractions. When reading, one purposefully directs one's attention from one word to the next, tuning out noise and other distractions. In natural behavior, endogenous and exogenous factors interact continuously to control the allocation of sensory processing (Egeth & Yantis, 1997).

Another important issue is *what* is attended. Attention can be directed to a location in space, regardless of what happens to be at that location. It can also be directed to a feature, as when one searches within a complex scene for an object of a particular shape or color. Attention can also select whole objects, as demonstrated by studies showing that when attention is directed to one feature of an object, the other features of the same object are selected automatically for visual processing and by studies finding that when attention is directed to one of two semitransparent objects, attending to a feature of one object impairs processing of the features of the other object. Finally, attention can select entire object categories in highly abstract ways (e.g., when you cross the street, you are looking for cars regardless of their different appearances). In each of these cases, attention has been found to facilitate processing of the attended location, feature, object, or object category, as assessed at the behavioral and neural levels (Peelen et al., 2009; Reynolds & Chelazzi, 2004).

Attention is thus highly flexible and can be deployed in a manner that best serves the organism's momentary behavioral goals: to locations, features, or objects, based on internal goals or the external environment, with or without accompanying orienting movements. It is important to keep in mind that although these phenomena can be isolated in laboratory experiments, all varieties of attention operate seamlessly during natural behavior.

NEGLECT SYNDROME: A DEFICIT OF SPATIAL ATTENTION

Studies of patients with brain lesions have identified regions of the brain that are involved in attention (see Fig. 46.1, which shows the major divisions of the human cortex). In the cortex, unilateral lesions in the parietal lobe, the frontal lobe, and the anterior cingulate cortex (Heilman, 1979; Vallar, 1993) in humans may cause a profound inability to attend to certain spatial regions, a syndrome known as spatial neglect. At the subcortical level, lesions of the basal ganglia or of the pulvinar thalamic nucleus, which is heavily connected with the parietal cortex, can also cause neglect. In severe cases, patients with neglect behave as if the world contralateral to their lesioned hemisphere (the contralesional world) has ceased to exist. For example, a patient with neglect following a right hemisphere lesion may fail to read from the left side of a book, may ignore the food on the left side of the plate, or may remain unaware of the numerals on the left side of a clock (Fig. 46.2). Neglect patients may also be reluctant to initiate movement in contralesional space, with or without external sensory stimulation. Because the critical feature causing an object to be ignored is its location, this type of neglect is thought of as primarily a disorder of spatial attention.

The behavioral impairments in neglect cannot be explained by simple sensory or motor deficits (Mesulam, 1999). Neglect patients have normal vision in the contralesional visual field once their attention has been directed there, and they have no hemiparesis that could account for their reluctance to move. In addition, the extent of their difficulty is not immutable, as a sensory or motor deficit

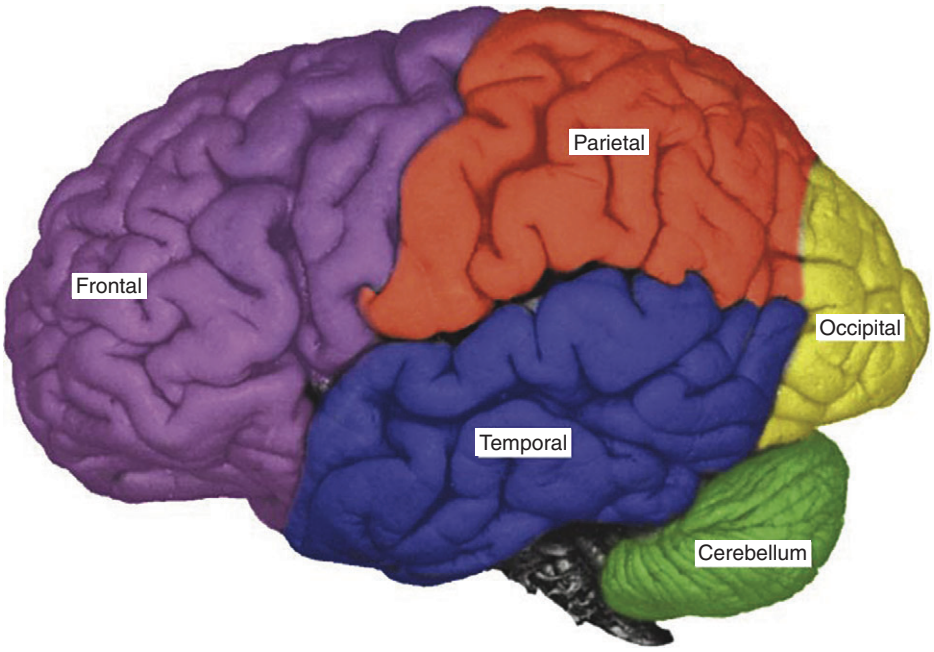

FIGURE 46.1 Lateral view of a human brain. Frontal (purple), parietal (orange), temporal (blue), and occipital (yellow) lobes are outlined.

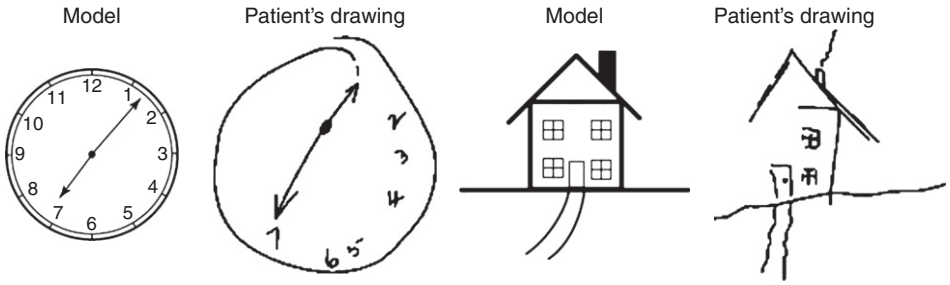

FIGURE 46.2 Two drawings that were made by a patient with spatial neglect. The patient was asked to copy the two models (clock, house). In each case, the copies exclude important elements that appeared on the left side of the model, indicating that the patient was unable to process information about the left side of the model.

would be, but is strongly affected by the goals, expectations, and motivational state of the patient. Thus, neglect represents a failure to select, in some circumstances, the appropriate portions of a sensory representation. Neglect operates on high-level representations that differ considerably from the raw sensory input. For example, visual neglect is not confined only to retinal visual coordinates (affecting only objects in the contralesional visual field) but can affect objects in the contralesional space relative to the patient's body, relative to the patient's gaze, or relative to an external object or scene. Thus, neglect affects a visual representation that incorporates information about the position of the body with high-level visual information. Neglect affects not only the perception of the present sensory environment, but also the processing of memorized or imagined scenes.

A related but milder attentional deficit, known as extinction, can follow more limited brain lesions or can occur during recovery from the acute phase of neglect. In visual extinction, patients are able to orient toward a contralesional stimulus presented in isolation, but fail to notice it if the same stimulus is presented simultaneously with an ipsilateral distracter. Extinction-like deficits are demonstrated readily with the spatial cuing task (Posner, Walker, Friedrich, & Rafal, 1984). In these tasks, subjects are cued to attend to the left or right visual field. Unimpaired observers are better able to process information at the cued location, but can also detect stimuli at an uncued location. Compared to unimpaired observers, neglect patients are slowed only mildly in their ability to detect targets in the contralesional visual field following valid symbolic or peripheral cues in the same field. However, they have enormously prolonged latencies for detecting contralateral targets if their attention had been misdirected to the ipsilesional field by means of an invalid cue. No impairment is seen when patients are cued to the contralesional field but asked to detect an ipsilesional target. Extinction-like phenomena also have been demonstrated in search tasks in which patients are asked to find a target object located at various locations in a complex

scene. The time needed to find a target in contralesional space increases in proportion with the number and salience of ipsilesional distracters.

ATTENTION AFFECTS NEURAL ACTIVITY IN THE HUMAN VISUAL CORTEX IN THE PRESENCE AND ABSENCE OF VISUAL STIMULATION

Human functional brain imaging studies are in agreement with both single-cell physiology and neuropsychological studies in identifying areas in the parietal, frontal, and cingulate cortices as being especially active in relation to spatially directed attention. When observers attend to a location in space in anticipation of the appearance of a stimulus, this is accompanied by elevated levels of activity in a fronto-parietal network consisting of the superior parietal lobule (SPL), the frontal eye field (FEF), and the supplementary eye field (SEF) extending into the anterior cingulate cortex (Fig. 46.3). This elevation in activity persists throughout the expectation period and when stimuli later appear at the attended location (Fig. 46.4B). It is important to note that the fronto-parietal attentional control network is not limited to controlling spatial attention. It is also activated when subjects select nonspatial information. Object- or feature-based attention engages the fronto-parietal attention network as well, indicating a general domain-independent mechanism of attentional control (Yantis & Serences, 2003).

Frontal and parietal areas have been associated with the control of spatial attention, but they are not usually considered crucial for visual processing or object recognition. There is converging evidence from event-related potential (ERP) and functional imaging studies that feedback signals from the fronto-parietal areas that control the allocation of attention can affect the neural processing of visual information in the human visual cortex. In a typical experiment, identical visual stimuli are presented simultaneously to corresponding peripheral field locations to the right and to the left of a central fixation point. Subjects are instructed to direct attention covertly to the right or the left by a symbolic cue presented at the fixation point and to detect the occurrence of a visual stimulus or, in some cases, discriminate a feature of the attended stimulus. Directing attention to the left hemifield increases stimulus-evoked activity in the extrastriate visual cortex of the right hemisphere, whereas directing attention to the right hemifield increases activity in the extrastriate

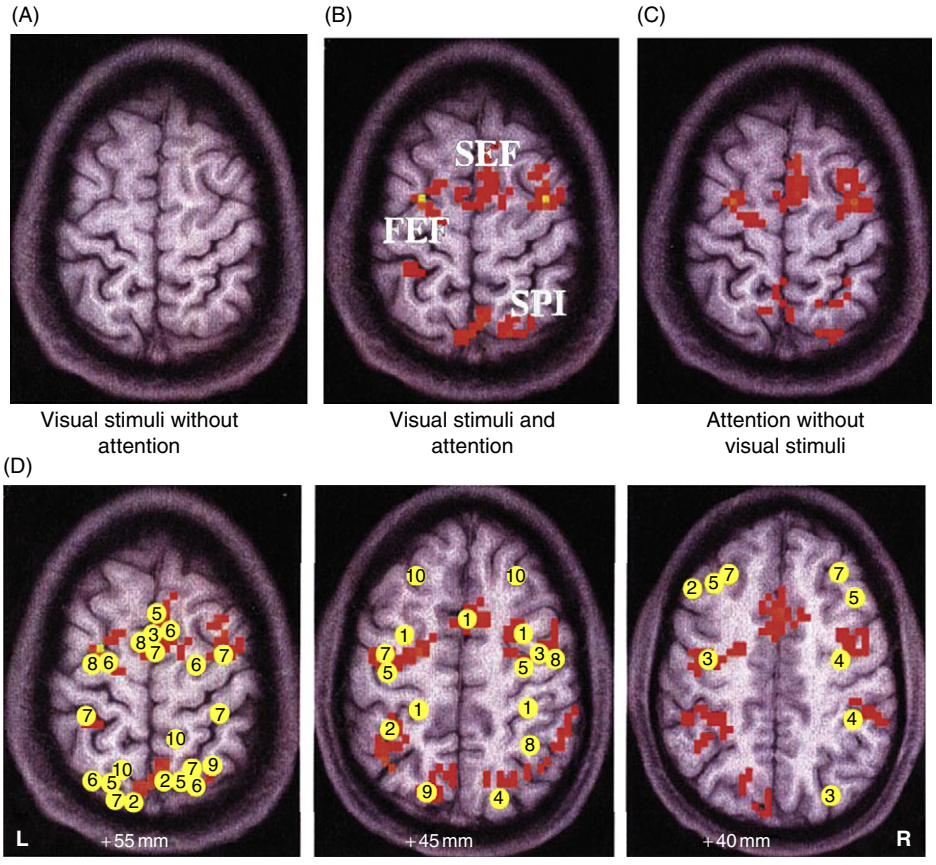

FIGURE 46.3 Regions in human brain activated by attention and regions associated with neglect. (A) Visual stimulation did not activate the frontal or parietal cortex reliably when attention was directed elsewhere in the visual field. (B) When the subject directed attention to a peripheral target location and performed an object discrimination task, a distributed fronto-parietal network was activated, including the SEF, the FEF, and the SPL. (C) The same network of frontal and parietal areas was activated when the subject directed attention to the peripheral target location in the expectation of the stimulus onset—in the absence of any visual input whatsoever. This activity therefore may not reflect attentional modulation of visually evoked responses, but rather attentional control operations themselves. (D) Meta-analysis of studies investigating the spatial attention network. Axial slices at different Talairach planes are indicated. Talairach (peak) coordinates of activated areas in the parietal and frontal cortex from several studies are indicated (For references, see Kastner & Ungerleider, 2000). R, right hemisphere; L, left hemisphere.

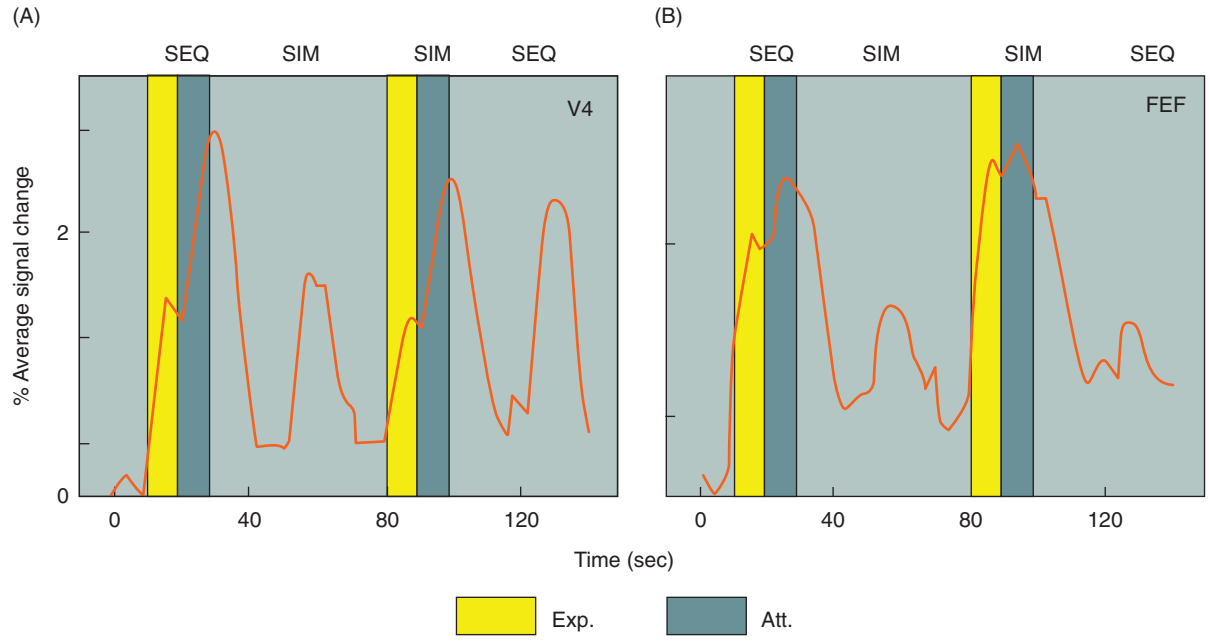

FIGURE 46.4 Directed attention in humans with and without visual stimulation. (A) Time series of fMRI signals in V4. Directing attention to a peripheral target location in the absence of visual stimulation led to an increase of baseline activity (textured blocks), which was followed by a further increase after the onset of stimuli (gray-shaded blocks). Baseline increases were found in both the striate and the extrastriate visual cortex. (B) Time series of fMRI signals in FEF. Directing attention to the peripheral target location in the absence of visual stimulation led to a stronger increase in baseline activity than in the visual cortex; the further increase of activity after the onset of stimuli was not significant. Sustained activity was seen in a distributed network of areas outside the visual cortex, including SPL, FEF, and SEF, suggesting that these areas may provide the source for the attentional top-down signals seen in visual cortex. *Adapted from Kastner et al. (1999).*

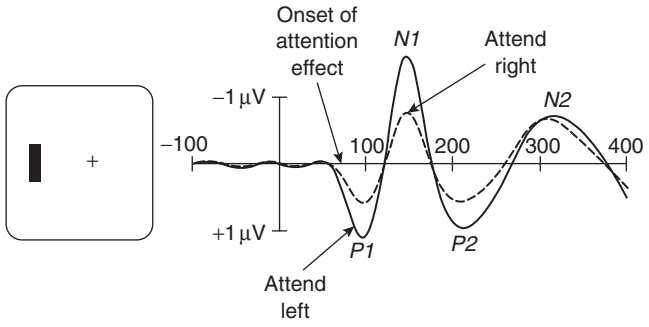

FIGURE 46.5 Attentional modulation of event related potentials (ERPs). In a typical experiment, subjects fixate a central cross and attend either to the left or right visual field. Stimuli are then presented to the left and right visual fields in a rapid sequence. This idealized example illustrated the common finding that the average ERP elicited by an attended visual field stimulus contains larger P1 and N1 components.

visual cortex of the left hemisphere (Heinze et al., 1994) (Fig. 46.5). Thus, responses to stimuli are enhanced on the side of the extrastriate cortex that contains representations of the attended hemifield. As is the case in the fronto-parietal areas, this increase in response is observed during the period prior to appearance of a stimulus, reflecting the effects of feedback signals from the attentional control areas.

In one imaging study (Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999), subjects were cued to direct attention covertly to a target location in the periphery of the visual field and to anticipate the onset of visual stimuli. Visual stimuli occurred with a delay of several seconds. Neural activity associated with spatially directed attention in the absence and in the presence of visual stimulation could therefore be distinguished. As was the case in the fronto-parietal control network, fMRI signals increased when attention was directed to the target location and before any visual stimulus was present on the screen. This increase in baseline activity was followed by an additional increase when stimuli appeared at the attended location (Fig. 46.4A), reflecting attention-dependent increases in the stimulus-evoked response itself. These studies and related single-unit studies in the monkey show that spatial attention effects are topographically organized and retinotopically specific, resulting in increased activity among neurons coding the attended location. Taken together, these findings suggest that an important way that spatial attention modulates visual processing is by amplifying the neural signals for stimuli at an attended location.

Functional brain imaging studies and single-unit recording studies in nonhuman primates have found evidence that nonspatial attention also modulates sensory cortices. One such study found that selective attention to shape, color, or speed enhanced activity in the regions of the extrastriate visual cortex that selectively process these same attributes. Attention to shape and color led to response enhancement in regions of the posterior portion of the fusiform gyrus, including area V4. Attention to speed led to response enhancement in areas MT/MST (Corbetta, Miezin, Dobmeyer, Shulman, & Petersen, 1991). In other studies, attention to faces or houses led to response enhancement in areas of the midanterior portion of the fusiform gyrus, areas responsive to the processing of faces and objects. These results support the idea that selective attention to a particular stimulus attribute modulates neural activity in those extrastriate areas that preferentially process the selected attribute.

SINGLE UNIT RECORDING STUDIES IN NONHUMAN PRIMATES PROVIDE CONVERGENT EVIDENCE FOR A FRONTO-PARIETAL ATTENTIONAL CONTROL SYSTEM

Studies in monkeys have supported the conclusion that frontal and parietal cortices play a role in controlling the allocation of attention (Bushnell et al., 1981). These studies point to two interconnected areas, one in the parietal cortex, the lateral intraparietal area (LIP), and one in the frontal lobe, the frontal eye field (FEF), as being important for spatial attention. Many neurons in FEF and LIP have spatially selective visual receptive fields, meaning that they respond to visual stimuli that activate a limited region of the retina. These receptive fields are retinotopic (they are linked to the retina and move relative to the external world every time the eye moves) and mostly contralateral, so that the FEF and LIP in one side of the brain represent the locations of objects in the contralateral portion of the visual field. Thus, the neurons provide a map of stimulus location in retinotopic coordinates.

Unlike the maps found in early visual areas (including the retina itself), the maps in LIP and FEF do not indicate the mere presence of an object in the world but respond selectively to objects that are likely to be attended, whether by virtue of their physical properties (conspicuity) or behavioral relevance. This was shown in a task where monkeys made eye movements (saccades) across a stable visual background, such that inconspicuous objects moved in and out of a neuron's receptive field (Gottlieb et al., 1998). LIP neurons responded little if a stable object entered their receptive field (Fig. 46.6A, center). However, they responded strongly if the identical object was presented with an abrupt onset that rendered it salient. Neural responses are strong if the object appears directly in the receptive field as is commonly the case in physiological experiments, but also if the object appears elsewhere and enters the receptive field a fraction of a second later by virtue of the subject's eye movement (A, right). An additional experiment showed that neurons also respond to stimuli that are not physically salient but become relevant, for example, by being selected as the target of the next saccade (B). These findings suggest that LIP integrates bottom-up and top-down factors relevant for attention and encode the priority of objects in the world. A similar proposal has been advanced for the FEF, and may also hold for area 7a, a parietal area adjacent to LIP (Constantinidis & Steinmetz, 2001).

A subsequent experiment linked the selective responses in LIP with attention measured behaviorally, as a transient enhancement of perceptual sensitivity (Bisley & Goldberg, 2003). In this experiment monkeys were shown a brief visual stimulus whose location they had to remember for a later saccade. During the memory period, a salient but irrelevant distractor flashed in the visual field. The authors measured the locus of attention at different times and locations by using a secondary contrast discrimination task. Even though the eyes remained still during the memory period, attention shifted—moving to the distractor location immediately after the flash and back to the saccade target later during the delay period. These dynamics were encoded in the neural activity in LIP: attention was pinned at the distractor location for as long as the LIP response to the distractor exceeded that to the target, and flipped to the saccade goal when the balance of activity shifted in LIP. Thus, the selective visual responses in LIP are driven both by salient and task-relevant stimuli and reflect the momentary locus of attention. Similar correspondences are found for FEF neurons in visual search tasks where subjects must direct attention to one of many stimuli in a display (Thompson & Bichot, 2005).

Direct evidence that LIP and FEF are involved in attention comes from experiments that chemically inactivate or microstimulate these areas and measure the effects of these manipulations on attention. Inactivation of the LIP or FEF using microinjections of muscimol (a GABA-A receptor agonist that temporarily silences spiking activity at the injection site) produces deficits in target selection during visual search. In the FEF, subthreshold microstimulation biases covert attention toward the location represented by the neurons at the stimulation site. Microstimulation of the FEF also modulates neural activity at corresponding locations in area V4, consistent with the idea that FEF neurons send top-down feedback to earlier visual areas.

In addition to modulating visual processing, LIP and FEF influence saccade motor planning through their

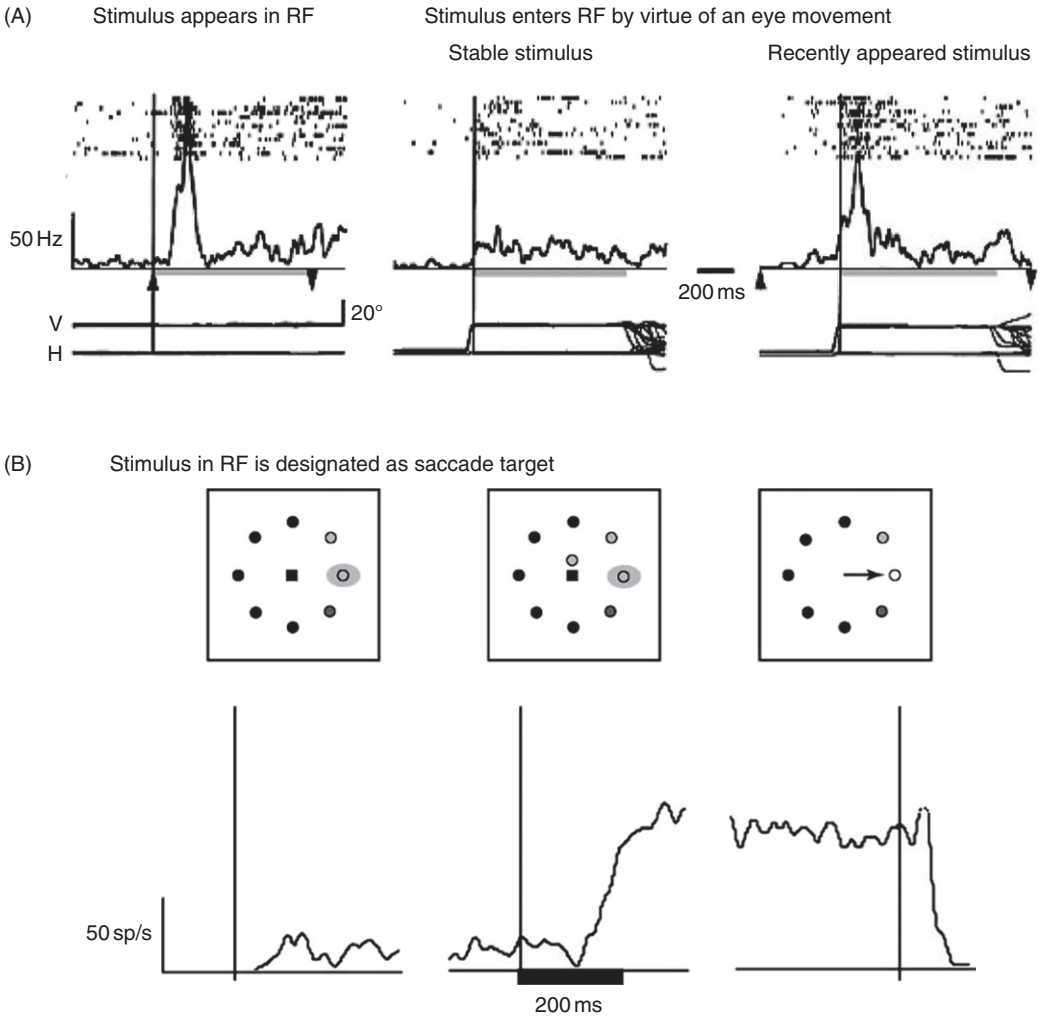

FIGURE 46.6 LIP neurons encode a spatial salience representation. (A) LIP neurons are sensitive to the physical conspicuity of objects in the receptive field. An LIP neuron responds strongly when a visual stimulus is flashed in its receptive field (left). The same neuron does not respond if the physically identical stimulus is stable in the world and enters the receptive field by virtue of the monkeys' eye movement (center). The neuron again responds if the stimulus entering the receptive field is rendered salient by flashing it on and off on each trial (before it enters the receptive field). In each panel, rasters show the times of individual action potentials relative to stimulus onset (left) or the eye movement that brings the stimulus in the receptive field (center and right). Traces underneath the rasters show average firing rate. Bottom traces show the horizontal and vertical eye position. The rapid eye movement (saccade) that brings the stimulus in the receptive field is seen as the abrupt deflection in eye position traces. (B) LIP neurons are sensitive to the behavioral relevance of objects in the receptive field. Traces show average firing rate of an LIP neuron when the monkey is cued to make a saccade to a stimulus in the receptive field. In the left panels the monkey is fixating and a stable stimulus is in the receptive field. The neuron has low firing rate. In the center panel the monkey receives a cue instructing him to make a saccade to the receptive field. The neuron gradually increases its response. In the right panel the monkey executes the instructed saccade. The neural response remains high until after the eye movement.

descending connections to the superior colliculus and brainstem oculomotor centers. Microstimulation and neural recordings suggest that these areas form a continuum of visuo-motor transformation, with LIP having primarily a visual role and the FEF being related to both visual selection and oculomotor output. Consistent with this idea, thresholds for electrically evoking saccades are high in LIP but much lower in the FEF. This suggests that LIP is more closely related to visual selection whereas FEF has a stronger influence on eye movement output. Similarly, neural recording studies show that LIP neurons are more closely related to visual selection whereas FEF encodes both visual selection and oculomotor output. In these studies monkeys are trained to make eye movements toward blank spatial locations, which may be *opposite* a salient visual cue, dissociating visual and motor selection. Such tasks show that LIP neurons predominantly encode stimulus location but provide scant motor information, responding only weakly before nonvisually guided saccades. The FEF contains a population of neurons that are predominantly sensitive to visual cues, but also contains neurons with mixed visuo-motor properties

and a small class of neurons—"movement neurons"—that are tightly coupled with saccade output. These neurons respond to saccades but not to simple visual inputs and ramp their responses to a constant level (threshold) prior to a saccade, suggesting that they reflect a fixed saccade threshold. These findings suggest that the brain implements a continuous transformation starting with a stage of visual selection mediated by visual and visuo-motor neurons in LIP and FEF, and culminating in motor selection mediated by movement neurons in FEF.

The properties of LIP and FEF neurons described above have lent support to the idea that the attentional system uses a central stage of visual selection—a "salience" or "priority map" that indicates a common currency for directing attention (Fig 46.7). Computational vision models show that systems that contain such a centralized architecture are more efficient than those implementing a more distributed selection in feature-specific visual areas. In the latter case attention would be allocated through competition between saliency signals in individual feature domains: for example, a color-selective area may tend to direct attention to a location of a color pop-out, competing with a motion selective area that attracts attention to a location with salient motion. By allowing these separate feature signals to converge to a common stage the brain can more efficiently coordinate visual selection as well as coordinate selection with action.

Experiments in recent years have begun to address a related and equally important question: namely, how are attention and eye movements coordinated with an ongoing task? How do neurons in FEF and LIP "know" which of the many available stimuli is related to one's current actions? The answer that is emerging from recent work suggests that this learning may be mediated by feedback regarding actions and reward to selective visual representations.

Studies from multiple laboratories show that visual selection response in LIP is not stereotyped but is shaped by the task associations of the attended stimulus. Among the factors modulating LIP activity are the shape or color of a search target, the statistical relationship between a target and salient stimulus, and the category of a visual cue in a categorization task. Figure 46.8A shows an example of modulatory feedback related to the motor response with which a monkey reported a perceptual discrimination (Oristaglio, Schneider, Balan, & Gottlieb, 2006). Monkeys were trained to find a cue in an array of distractors, and, without shifting gaze to the cue, report the

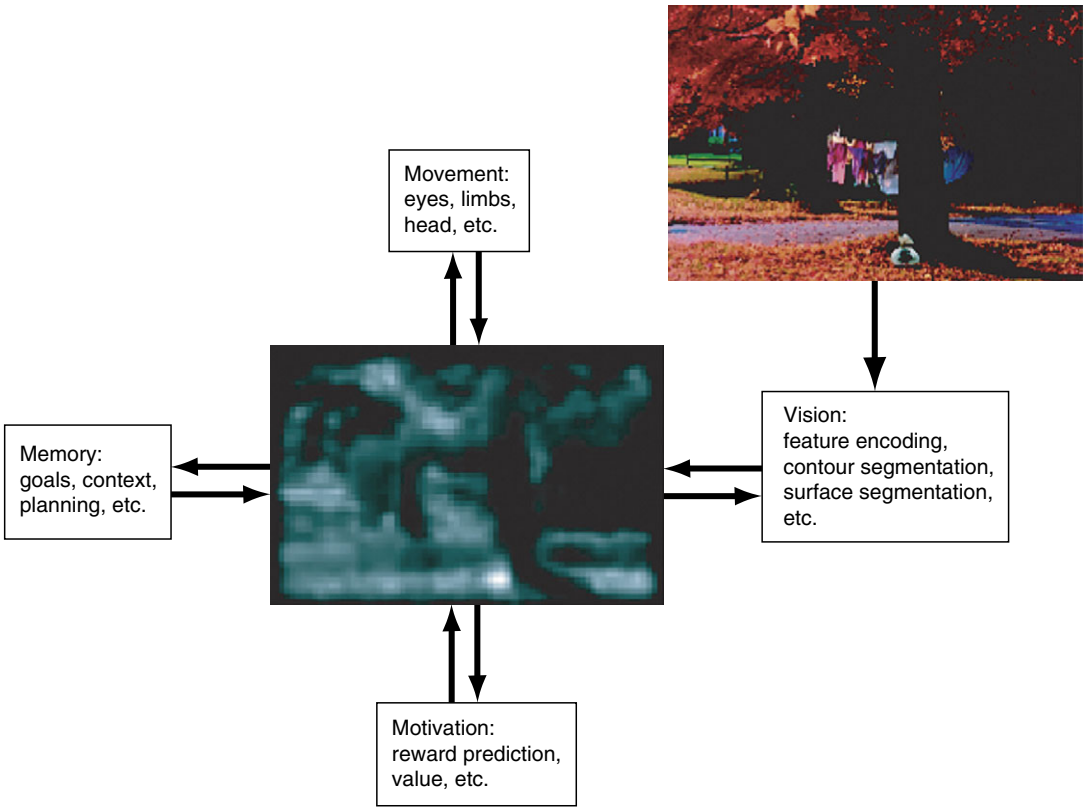

FIGURE 46.7 A salience representation can be viewed as an intermediate representation that interacts with multiple behavioral systems (visual, motor, cognitive, and motivational) and fashions a unified signal of "salience" based on multiple task demands. By virtue of feedback connections to these systems the salience map can help coordinate output processing in multiple "task-relevant areas."

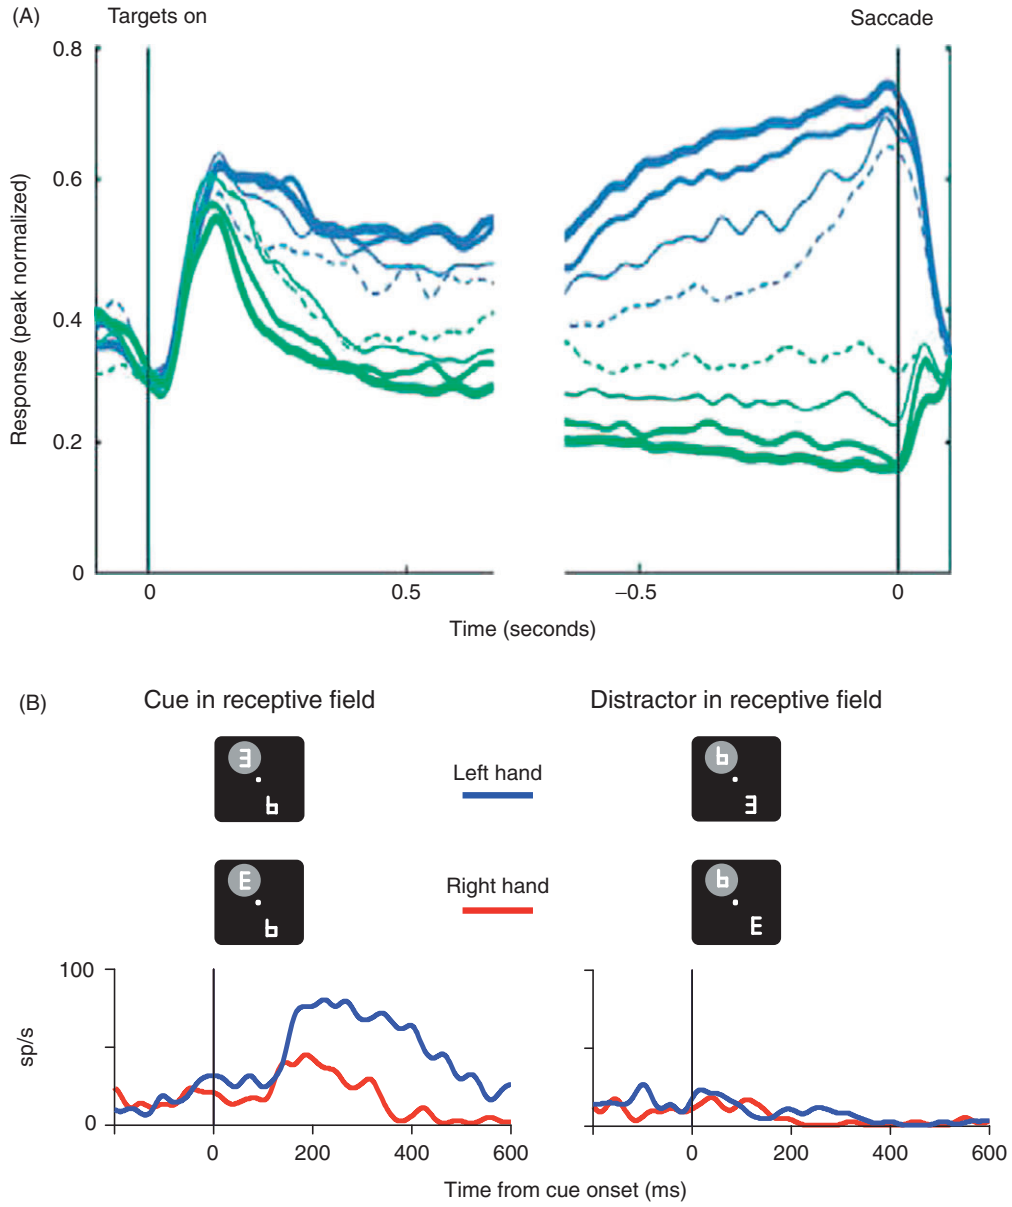

FIGURE 46.8 (A) LIP responses are modulated by reward probability. Monkeys performed a dynamic foraging task in which they tracked the changing reward values of each of two saccade targets. Traces represent population responses for neurons with significant effects of reward probability. Blue traces represent saccades toward the receptive field, and green traces represent saccades opposite the receptive field. Traces are further subdivided according to local fractional income (reward probability during the past few trials): solid thick lines, 0.75–1.0; solid medium lines, 0.5–0.75; solid thin line, 0.25–0.5; dotted thin lines, 0–0.25. Activity for saccades toward the receptive field increased, and that for saccades away decreased as function of local fractional income, resulting in more reliable spatial selectivity (difference between the two saccade directions) with increasing reward probability. (B) LIP neurons are modulated by limb motor planning. Monkeys viewed a display containing a cue (a letter "E") and several distracters. Without moving gaze from straight ahead, they reported the orientation of the cue by releasing one of two bars grasped with their hands. The neuron illustrated here responded much more strongly when the cue rather than a distracter appeared in its receptive field (left versus right panels). This cue-related response was modulated by the manual release: the neuron responded much more when the monkey released the left than when she released the right bar (blue versus red traces). Limb modulations did not always accompany a bar release, but were found only when the attended cue was in the receptive field. Bar-release latencies were on the order of 400–500 ms.

orientation of the cue with a manual release. Monkeys reported whether the cue was right- or left-facing by releasing a bar grasped with, respectively, their right or left paw. LIP neurons responded much more strongly to a cue, relative to a distractor, in their receptive fields (Fig. 46.8A, left vs. right panels). Thus, neurons encoded the location of the cue, as would be expected based on previous work. Unexpectedly, however, the cue selection response was modulated by the monkey's choice of limb. The neuron illustrated in Figure 46.8A responded more

strongly to the cue in its receptive field if the monkey released the left bar than if she released the right bar, while other neurons showed the opposite preference, responding more for right than for left bar release. This finding was surprising because the motor response was nontargeting—not directed to a particular spatial location—and was performed outside the monkey's field of view. Thus, the visual selection signal in LIP was modulated by a nonspatial variable, the limb that was associated with the selected visual cue. While the significance of this nonspatial signal is not yet fully understood, an intriguing possibility is that it may represent feedback through which the brain learns the relation of the cue to a particular motor output and hence, its "relevance" in the behavioral task.

A particularly significant source of feedback carries information about expected reward. An illustration of reward effects in LIP comes from an experiment where monkeys were free to choose between two saccade directions (either toward or away from the receptive field), and the probability that any one direction would be rewarded was systematically varied (Fig. 46.8B; Sugrue, Corrado, & Newsome, 2004). Monkeys apportioned their choices in relation to reward probability, tending to choose the target with the higher probability of reward. LIP responses to the selected target increased as a function of reward probability (blue traces). A later experiment showed that reward expectancy modulates responses to salient stimuli even if these are not saccade targets, consistent with the predominantly visual nature of the selective response in LIP (Peck, Jangraw, Suzuki, Efem, & Gottlieb, 2009). This suggests that priority maps may associate stimuli with rewards, possibly guiding attentional allocation so as to optimize performance in a task.

ATTENTION INCREASES NEURONAL RESPONSES AND BOOSTS THE CLARITY OF SIGNALS GENERATED BY NEURONS IN PARTS OF THE VISUAL SYSTEM DEVOTED TO PROCESSING INFORMATION ABOUT OBJECTS

Consistent with the previously mentioned functional imaging studies, single-unit recording studies in the visual cortices have found that when attention is directed to a single stimulus in the receptive field, there is often an increase in the firing rates of neurons that respond to the attended stimulus (Reynolds & Chelazzi, 2004). This is illustrated in Figure 46.9A. On the left is the average firing rate of an individual neuron recorded in macaque Area V4. The neuron's response was higher when the monkey attended to the stimulus within the neuron's receptive field (red line) than when attention was directed away to a distant stimulus (blue). This attention-dependent increase in mean firing rate is typically observed when attention is directed toward a single neuron within the receptive field, as shown in the middle figure of A, which shows the distribution of attentional modulation across the population, with positive values corresponding to neurons exhibiting attention-dependent increases in mean response and negative values corresponding to reductions. Gray bars indicate neurons whose mean firing rates were not significantly modulated by attention. In addition to this modulation of mean firing rate, attention also reduces the variability of the neuronal response over time (Mitchell, Sundberg, & Reynolds, 2007). This is illustrated in the rightmost figure of A. Here, positive values correspond to neurons whose responses became more variable ("noisier") when attention was directed toward the stimulus within the receptive field, and negative values, to neurons whose responses became less variable.

How much does this reduction in variability translate into improved signaling across a neuronal population? This depends on whether the variability of neuronal responses that is reduced by attention is correlated across the neuronal population. Variability that is *uncorrelated* can be averaged away when the population responses are pooled by a downstream neuron, but *correlated* variability cannot be averaged out. Cortical neuronal responses are typically somewhat correlated with one another (Harris & Thiele, 2011), as shown in Figure 46.9B. Here, neuronal responses were recorded simultaneously from two neurons, and the spiking responses were summed over brief time intervals. The resulting spike counts for a pair of V4 neurons are shown in the blue panel on the left. The responses of the two neurons were correlated, with stronger responses in Neuron 1 typically being accompanied with stronger responses in Neuron 2. This correlation was substantially reduced when attention was directed toward the stimulus that fell within the two neurons' receptive fields, as illustrated in the red panel, center. Across the population, this firing rate correlation was diminished by approximately one-half, as shown in the panel on the right (Mitchell, Sundberg, & Reynolds, 2009).

So attention modulates the mean firing rates of neurons (a change in their *gain*) and simultaneously decorrelates the moment-to-moment variability in individual neurons' firing rates. Theoretical calculations enable us to calculate the improvement in the signal quality (*signal-to-noise ratio*) resulting from these increases in the gain and reductions in correlation of the afferent responses (Zohary, Shadlen, & Newsome, 1994). This is illustrated in the left figure of Figure 46.9C, which shows the signal-to-noise ratio of the pooled signal as a function of the number of neurons in the pool. If the interneuronal variability is uncorrelated, the signal-to-noise ratio increases linearly with the logarithm of the number of neurons in the pool (straight line). If neuronal variability is correlated across neurons, this imposes an upper bound on the signal-to-noise ratio of

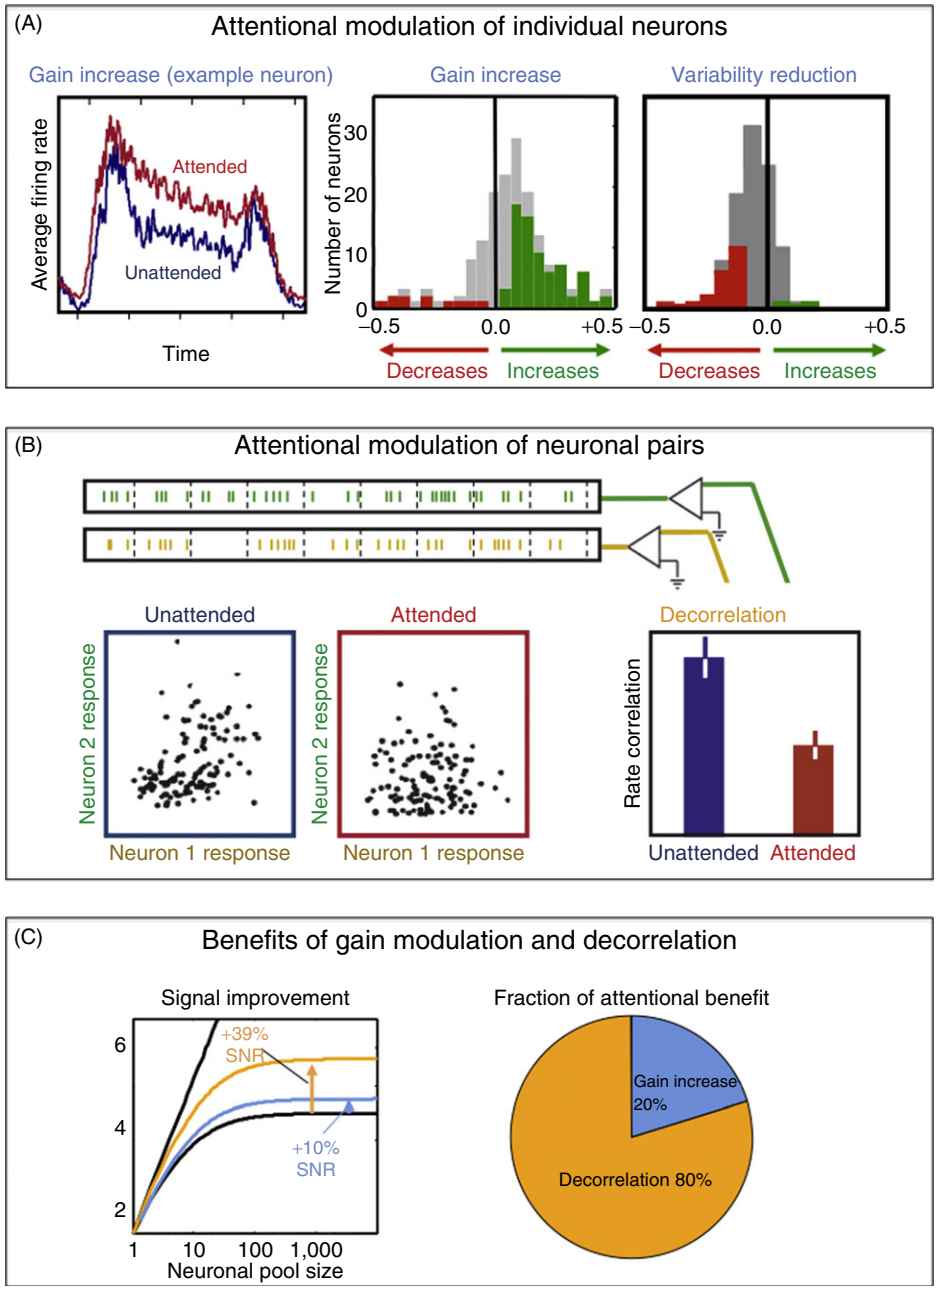

FIGURE 46.9 Attention increases the mean firing rates of individual neurons and the degree to which their firing rates covary over time. (A) Attention-dependent increases in firing rate. (B) Attention-dependent reductions in response covariation. (C) Under the assumption that downstream neurons pool the signals of the afferent neuronal population, observed levels of attention-dependent decorrelation of low-frequency (<10 Hz) fluctuations in firing rate result in increases in signal quality four times as large as the improvement attributable to increases in firing rate.

the pooled signal. This is shown in the saturating black curve, which was calculated based on correlations actually observed in macaque V4 neurons when attention was directed away from the stimulus. The blue line shows the modest increase in asymptotic signal quality that results from the measured attention-dependent increase in gain. The yellow line shows the comparatively larger increase in signal quality that results from observed attention-dependent reductions in low-frequency response correlations (Mitchell et al., 2009). The improvements due to gain and decorrelation are shown in the figure to the right. Decorrelation accounts for the lion's share of attention-dependent improvement in signal quality (Cohen & Maunsell, 2009; Mitchell et al., 2009).

Microstimulation studies support the conclusion that attention-dependent changes in firing rate within the visual cortices result from feedback signals that are generated in the fronto-parietal attentional control network. Moore and Armstrong (2003) measured the locations in FEF where stimulating current would move the eyes, the "movement field" of the stimulation site. They then reduced the stimulating current to a level too low to evoke an eye movement, and observed the effect of this stimulation on the responses of neurons in visual area V4. They

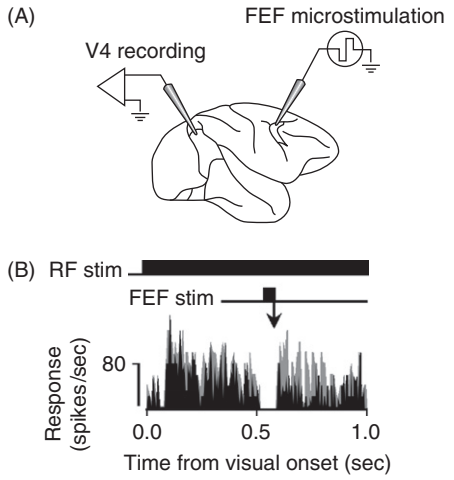

FIGURE 46.10 Electrical stimulation of FEF increases neuronal responsiveness in V4. (A) Current was injected into FEF while neuronal activity was recorded from V4. (B) The visual stimulus appeared in the receptive field for one second (RF stim). 500 ms after the onset of the visual stimulus, a low level of current was applied to a site in FEF for 50 ms (FEF stim). The response of a single V4 neuron with (gray) and without (black) FEF microstimulation appears below. The apparent gap in response reflects the brief period during which V4 recording was paused while current was injected into FEF, when, for technical reasons, the stimulating current interfered with the ability to record action potentials. Following stimulation, the V4 neuron had elevated responses on trials when FEF was electrically stimulated, as compared to trials without FEF stimulation.

found that FEF stimulation caused V4 neurons to respond more robustly to a stimulus that appeared at the movement field within the V4 neuron's receptive field (Fig. 46.10A). Figure 46.10B shows responses of a single V4 neuron with and without stimulation. The time course of stimulus presentation (RF stim) and current injection (FEF stim) are illustrated at the top of the panel. The neuronal responses in the two conditions are indicated at the bottom of the figure. Stimulation was injected 500 ms after the appearance of the stimulus, at which point the stimulus-evoked response had begun to diminish in strength. The average response on microstimulation trials (gray) was elevated following electrical stimulation, relative to nonstimulation trials.

ATTENTION MODULATES NEURAL RESPONSES IN THE LATERAL GENICULATE NUCLEUS

The lateral geniculate nucleus (LGN) is the thalamic station in the retinocortical projection and traditionally has been viewed as the gateway to the visual cortex. In addition to retinal afferents, the LGN receives input from multiple sources including striate cortex, the thalamic reticular nucleus (TRN), and the brainstem. The LGN therefore represents the first stage in the visual pathway at which cortical top-down feedback signals could affect information processing.

It has proven difficult to study attentional response modulation in the LGN using single-cell physiology due to the small RF sizes of LGN neurons and the possible confound of small eye movements. Initially, several single-cell physiology studies failed to demonstrate attentional modulation in the LGN, supporting a notion that selective attention affects neural processing only at the cortical level. This notion was first revisited using fMRI in humans (O'Connor, Fukui, Pinsk, & Kastner, 2002). As in visual cortex, different modulatory effects of attention were found. Neural responses to attended visual stimuli were enhanced relative to the same stimuli when unattended. As in cortex, this effect of attentional response enhancement was shown to be spatially specific in the LGN. And directing attention to a location in the absence of visual stimulation and in anticipation of the stimulus onset increased neural baseline activity. Together, these studies indicate that the LGN appears to be the first stage in the processing of visual information that is modulated by attentional top-down signals.

These studies were suited to compare the magnitude of the attention effects across the visual system. The magnitude of all attention effects increased from early to more advanced processing levels along both the ventral and dorsal pathways of visual cortex. This is consistent with the idea that attention operates through top-down signals that are transmitted via cortico-cortical feedback connections in a hierarchical fashion. This idea is supported by single-cell recording studies, which have shown that attention effects in area TE of inferior temporal cortex have a latency of approximately 150 ms, whereas attention effects in V1 have a longer latency of approximately 230 ms. According to this account, one would predict smaller attention effects in the LGN than in striate cortex. Surprisingly, it was found that all attention effects tended to be larger in the LGN than in striate cortex. This finding suggests that attentional response modulation in the LGN is unlikely to be due solely to corticothalamic feedback from striate cortex, but may be further influenced by additional sources of input. In addition to corticothalamic feedback projections from V1, which comprise about 30% of its modulatory input, the LGN receives another 30% of modulatory inputs each from the TRN and the parabrachial nucleus of the brain stem. This view has been corroborated by a recent physiology study (McAlonan, Cavanaugh, & Wurtz, 2008) that demonstrated concurrent response modulation in parvo- and magnocellular LGN and the TRN. While the response amplitudes evoked by an attended stimulus increased relative to those evoked by unattended stimuli in the LGN, they decreased in the TRN and also

preceded the LGN responses, suggesting a release of inhibitory control of the TRN over the LGN. These effects occurred in the first 100 ms after stimulus onset. A second effect of attention on the LGN manifested 200 ms after stimulus onset and was independent of the TRN. It is conceivable that this late response modulation reflects cortical feedback via V1. Given its afferent input the LGN may be in an ideal strategic position to serve as an early gatekeeper in attentional gain control.

THE VISUAL SEARCH PARADIGM HAS BEEN USED TO STUDY THE ROLE OF ATTENTION IN SELECTING RELEVANT STIMULI FROM WITHIN A CLUTTERED VISUAL ENVIRONMENT

So far this chapter has considered the situation when attention is cued to a location (or a feature) in the visual field. However, one is rarely told in advance to attend to a particular location. Normally, one needs to find a particular object in a complex world that is composed of a large number of stimuli. Psychologists have used a visual search paradigm to understand how attention selects behaviorally relevant stimuli out of a group of other stimuli.

In a typical task, observers are asked to search among an array of stimuli and indicate whether a particular target is present in the array. This task is easier under some conditions than others. For example, it is easy to determine whether a horizontal green bar is present in Figure 46.11A. It takes longer to make this judgment for stimuli in Figure 46.11B. Treisman and Gelade (1980) found that searches for a target with a unique feature, like the one illustrated in Figure 46.11A, can be completed quickly regardless of the number of elements in the search array; the target seems to "pop out" of the search array. Such searches often are referred to as efficient. In contrast, Treisman and Gelade (1980) found that the amount of time required to find a target that is defined by conjunctions of elementary features (e.g., a horizontal green among horizontal reds and vertical greens, as in Fig. 46.11B) increases linearly with the number of elements in the array. Such searches often are referred to as inefficient. The amount of time added per item depends on stimulus conditions, but a rule of thumb is that each additional item in the array adds about 50 ms to the amount of time taken to locate the target. The fact that it takes time to locate the target in Figure 46.11B implies that the visual system is limited in capacity. If it were not, the target could be identified immediately by evaluating every element in the array simultaneously.

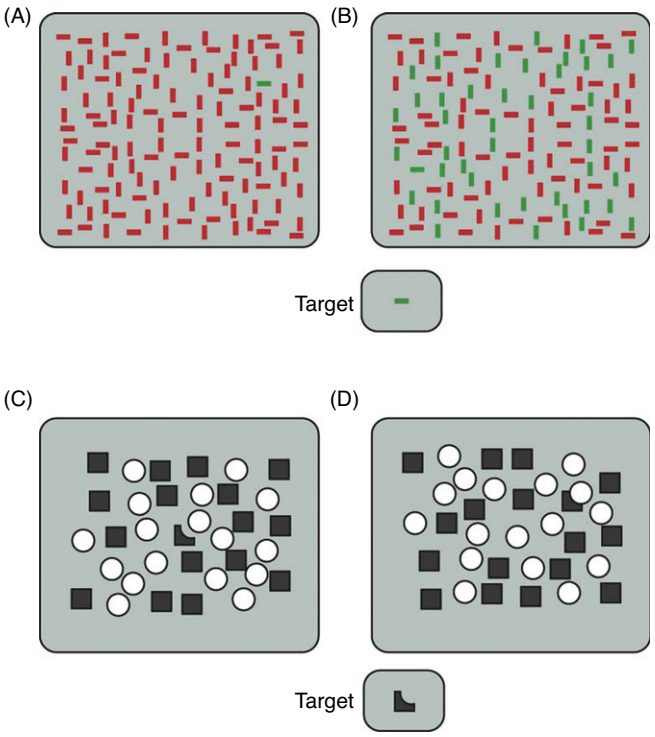

FIGURE 46.11 Efficient and inefficient visual searches. (A) Pop-out search. The horizontal green bar differs from all other array elements in a single feature, color. As a result, it pops out immediately, regardless of how many elements are in the array. (B) The same target is difficult to find when it is embedded among elements that cannot be differentiated from it on the basis of a single feature (color or orientation). (C) The dark target pops out among squares and circles. (D) When the same target is perceived to be a square occluded behind a circle, it is difficult to find among squares and circles. Because this arrangement of the array interferes with visual search, this suggests that integration of objects into wholes occurs prior to the activation of attentional mechanisms used in visual search. Thus, these mechanisms are evidently not necessary for completion. *Adapted from Rensink and Enns (1998).*

WHERE IS THE COMPUTATIONAL BOTTLENECK AS REVEALED BY SEARCH TASKS?

Considerable debate exists regarding the locus and nature of the computational bottleneck that causes the capacity limitations that are revealed by visual search tasks. One influential theory, feature integration theory (FIT; Treisman & Gelade, 1980), proposes that capacity limitations occur at very early stages of cortical processing where "elementary" features are bound into coherent objects. This theory proposes that in the "pop-out" case, where the target differs from distracters in a single elemental feature, a search can be completed efficiently because there is no need to bind together different elementary features. Thus, a green target among red distracters (Fig. 46.11A) can be found in parallel by V1 neurons that respond to green but not red stimuli, without the need

for visual attention. However, in a conjunction search, where each of the elementary target features (color and orientation) is shared with distracters, the observer must bind elementary features into coherent object representations before search can occur. According to this account, one cannot process multiple objects simultaneously because in order to avoid misconjoining features from different objects, attention selects features from one location at a time. Consistent with this idea, patient RM, who suffered damage to his parietal attentional control system, often misconjoins the shape and color of letters, even after viewing them for up to 10 seconds; that is, he mixes up which letters are presented in which colors.

However, the idea that limited capacity occurs at early stages of processing has been challenged. For example, some studies suggest that parts of objects are integrated into wholes prior to the application of attention. Consider the task of searching for the oddly shaped object appearing at the bottom of Figure 46.11 (adapted from Rensink & Enns, 1998). This odd shape pops out from among the squares and circles in Figure 46.11C, but it is harder to find the same shape in Figure 46.11D. The difference is that in Figure 46.11D, the oddly shaped part appears to be a square that is occluded by a superimposed circle; that is, the visual system completes the shape of the occluded square, hiding it among the other squares. Because this completion stops the square from popping out, the completion operation must occur prior to visual search.

Further evidence that features can be integrated preattentively into objects comes from the finding that when an observer attends to one feature of an object (e.g., its orientation), other features of the object are selected automatically as well. In a now classic study, Duncan (1984) found that observers could easily make simultaneous judgments about two features of the same object (e.g., its orientation and whether or not it contained a gap). Making the second judgment did not interfere with the first judgment. However, observers were severely impaired when they simultaneously judged the same two features, one on each of two different stimuli. This finding suggests that when attention is directed to one feature of an object, all the features that make up the object can automatically be selected together because the features are already linked together into objects. These sorts of observations suggest that limited capacity results from information processing bottlenecks that occur relatively late in processing, after features are already integrated into wholes. One possibility is that the bottleneck occurs when objects enter a limited capacity working memory. Under this view, attention plays the role of selecting which objects pass through the bottleneck.

These two perspectives are not mutually exclusive. Some feature integration may occur preattentively (e.g., Rensink & Enns, 1998), but other types of stimulus integration might require spatial selection. As described earlier, attention has been found to modulate neural activity at all stages of visual processing including early stages (Motter, 1993; O'Connor et al., 2002), where neuronal responses first show signs of grouping the features and parts of objects into wholes, as well as late stages, which are likely involved in selecting stimuli for storage in working memory. Thus, both early and late stages of processing may act as limited capacity bottlenecks.

NEURONAL RECEPTIVE FIELDS ARE A POSSIBLE NEURAL CORRELATE OF LIMITED CAPACITY

Extracellular recording studies of attention in awake, behaving monkeys have revealed that the receptive fields of individual neurons might contribute to the limitation in visual capacity. As visual information traverses the successive cortical areas of the ventral stream that underlie object recognition (Ungerleider & Mishkin, 1982), the sizes of receptive fields increase from less than a degree of visual arc in primary visual cortex (area V1) to about 20° of visual arc in area TE, the last purely visual area in the ventral visual processing stream (see Chapter 44). Similar increases in receptive field size are observed in the dorsal visual processing stream. In a typical scene, such large receptive fields will contain many different objects. Therefore, a likely explanation for why one cannot process many different objects in a scene simultaneously is that neurons, whose signals are limited in bandwidth, cannot simultaneously send signals about all the stimuli inside their receptive fields. This idea implies that processing limitations exist at all levels of processing but that they become more pronounced in higher order visual areas, where receptive field sizes are larger. How then do neurons transmit signals about behaviorally relevant stimuli in their receptive fields?

One proposal is that the selective processing of behaviorally relevant stimuli is accomplished by two interacting mechanisms: competition among potentially relevant stimuli and biases that determine the outcome of this competition. For example, when an observer is asked to detect the appearance of a target at a particular location, this task is thought to activate spatially selective feedback signals in cortical areas, such as parts of the parietal and frontal cortex discussed earlier. These cortical areas provide a task-appropriate spatial reference frame and transmit signals to the extrastriate cortex, where they bias competition in favor of stimuli that appear at the attended location. Similarly, when an observer searches for an object in a cluttered scene, feature-selective feedback is thought to bias competition in favor of stimuli that share features in common with the searched-for object. When competition is

resolved, the winning stimulus controls neuronal responses, and other stimuli are effectively filtered out of the visual stream.

Studies in monkeys have compared the effect of attention on neuronal responses with single and multiple stimuli in the receptive field. Consistent with the proposal just outlined, larger changes in firing rate occur when multiple stimuli appear within the receptive field (and one stimulus must be attended), as compared to when the attended stimulus appears alone and there is no competition to be resolved (Moran & Desimone, 1985). According to the biased competition model just described, neurons that respond to a stimulus should be suppressed when a second stimulus is added that activates a competing population of neurons. To test this idea, pairs of stimuli were presented that activated two nearby populations of neurons (Reynolds, Chelazzi, & Desimone, 1999). Monkeys attended away from the receptive fields of the neurons. The first stimulus was chosen to be of a color and orientation that would strongly activate the recorded neuron. Then, a second stimulus, which elicited a response in a nearby population of neurons, was added. As predicted, the addition of this second stimulus partially suppressed the responses of many neurons to the first stimulus. To test whether attentional feedback would resolve competition in favor of the neurons that responded to the attended stimulus, attention was then directed to the poor stimulus. As predicted, this often magnified the suppressive influence of the poor stimulus, further reducing the firing rates of many neurons (Fig. 46.12A). In a final experiment, attention was directed to the preferred stimulus. Consistent with the resolution of competition in favor of the neurons that responded to the preferred stimulus, directing attention to the preferred stimulus strongly reduced the suppressive effect of the poor stimulus (Fig. 46.12B).

These findings, and related studies conducted over the past decade, have led to increasingly refined models of attentional selection, grounding our understanding of the automatic gain control circuitry that adjusts visual sensitivity in response to variation in the strength of sensory input (Reynolds & Chelazzi, 2004). Gain control is necessitated by the enormous range of stimulus intensity, such as luminance, luminance contrast, and color contrast that occurs within the visual environment. Take, for example, the change in the number of photons that enter the eye. This varies a million fold from a moonlit night to a sunny day. Evolution has endowed us with a variety of automatic gain control mechanisms, which, together, help us to remain sensitive to subtle changes in sensory input in the face of such enormous variation in intensity. These mechanisms range from the pupillary response to gain control mechanisms within the retina, the lateral geniculate nucleus, and the visual cortices. Decades of research in anesthetized animals have elucidated these neural

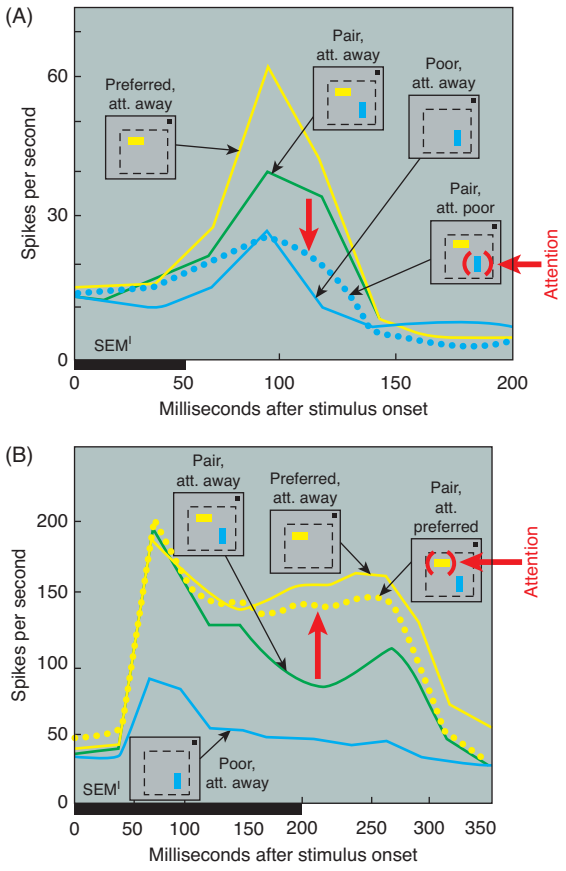

FIGURE 46.12 Attention to one stimulus of a pair filters out the effect of the ignored stimulus. (A) The x-axis shows time (in milliseconds) from stimulus onset, and the thick horizontal bar indicates stimulus duration. Small iconic figures illustrate sensory conditions. Within each icon, the dotted line indicates the receptive field, and the small dot represents the fixation point. The location of attention inside the receptive field is indicated in red. Attention was directed away from the receptive field in all but one condition. The preferred stimulus is indicated by a horizontal yellow bar and the poor stimulus by a vertical blue bar. In fact, the identity of both stimuli varied from cell to cell. The yellow line shows the response of a V2 neuron to the preferred stimulus. The solid blue line shows the response to the poor stimulus. The green line shows the response to the pair. The addition of the poor stimulus suppressed the response to the preferred stimulus. Attention to the poor stimulus (red arrow) magnified its suppressive effect and drove the response down to a level (dotted blue line) that was similar to the response elicited by the poor stimulus alone. (B) Response of a second V2 neuron. The format is the same as in A. As in the neuron above, the response to the preferred stimulus was suppressed by the addition of the poor stimulus. Attention directed to the preferred stimulus filtered out this suppression, returning the neuron to a response (dotted yellow line) similar to the response that was elicited when the preferred stimulus appeared alone inside the RF. *Adapted from Reynolds et al. (1999).*

mechanisms, and it appears that the attentional system has co-opted some of them, including suppressive circuitry within the striate and extrastriate visual cortices. Models in which these gain control circuits are modulated by feedback from attentional control centers have proven

able to account for attention-dependent changes in sensitivity, and competitive selection of task-relevant stimuli from among task-irrelevant distracters (Reynolds et al., 1999; Reynolds & Heeger, 2009). It thus appears that while automatic gain control mechanisms may originally have evolved to act in response to changes in the external environment, they also play a key role in endogenously generated attentional selection.

FILTERING OF UNWANTED INFORMATION IN HUMANS

Functional brain imaging studies suggest that in the human visual cortex, just as in the monkey cortex, mechanisms exist such that multiple stimuli compete for neural representation and unwanted information can be filtered out (Kastner, De Weerd, Desimone, & Ungerleider, 1998). In one fMRI study, subjects maintained fixation while they were presented with colorful visual stimuli in four nearby locations in the periphery of the visual field (Kastner et al., 1998). Stimuli were presented under two different conditions. In a sequential condition, a single stimulus appeared in one of the four peripheral locations, then another appeared in a different location, and so on, until each of the four stimuli had been presented in the four different locations. In a simultaneous condition, the same four stimuli appeared in the same four locations, but they were presented at the same time. Thus, physical stimuli were identical in the two conditions except that in the second case, all four stimuli appeared simultaneously, which should encourage competitive interactions among the stimuli. The subjects' task was to count letters at fixation, thereby ignoring the peripheral stimulus presentations. Activation of V1 and ventral stream extrastriate areas V2 to TEO was found under both presentation conditions. Although the fMRI signal was similar in the two presentation conditions in V1, activation was reduced in the simultaneous condition compared to the sequential condition in V2. This reduction in activity was especially pronounced in V4 and TEO. The most straightforward interpretation of this result is that simultaneously presented stimuli interacted in a mutually suppressive way. This sensory suppression effect may be a neural correlate of competition in the human visual cortex. Importantly, the suppression effects appeared to be scaled to the receptive field size of neurons within visual cortical areas; that is, the effects were larger in areas with larger receptive fields. This observation suggests that, as in the monkey visual cortex, competitive interactions occur most strongly at the level of the receptive field (Kastner et al., 1998).

The effects of spatially directed attention on multiple, competing visual stimuli have been studied in a variation of the same paradigm (Kastner et al., 1998). In addition to the two different visual presentation conditions, sequential and simultaneous, two different attentional conditions were tested, unattended and attended. During the unattended condition, attention was directed away from the visual display by having subjects count the occurrences of letters at the fixation point. In the attended condition, subjects were instructed to attend covertly to the stimulus location that was closest to the fixation point and to count the occurrences of one of the four stimuli. The attended condition led to greater increases in fMRI signals to simultaneously presented stimuli than to sequentially presented stimuli. Thus, in this case, attention partially cancelled out the suppressive interactions among competing stimuli. The magnitude of the attentional effect was greater where the suppressive interactions among stimuli had been strongest, such that the strongest reduction of suppression occurred in areas V4 and TEO. These findings support the idea that directed attention enhances information processing of stimuli at attended locations by counteracting the suppression induced by nearby stimuli that are competing for limited processing resources. In this way, unwanted distracting information is filtered out effectively.

Unwanted information can not only be filtered out effectively by top-down mechanisms that resolve competitive interactions among multiple objects, but also by bottom-up mechanisms that are defined by the context of the stimuli. As we have seen earlier, if a salient stimulus is present in a cluttered scene, it will be effortlessly and quickly detected regardless of the number of distracters, suggesting that competition is biased in favor of the salient stimulus. It has been shown that bottom-up influences related to stimulus context of a visual display such as a single, salient stimulus that pops out from a homogeneous, or several stimuli that are grouped together by a Gestalt rule such as collinearity or similarity can partially or even entirely overcome competitive interactions in a multiple-stimulus display. A pop-out display condition, in which a single item differed from the others, was compared to a heterogeneous display, in which all four stimuli were different. Subjects were engaged in a difficult letter detection task at fixation and never attended to the pop-out or heterogeneous displays that were shown in the periphery of the visual field. Competitive interactions among multiple stimuli were eliminated in area V4 when the stimuli were presented in the context of pop-out displays relative to heterogeneous displays, indicating that competition was biased in favor of the salient stimulus in a bottom-up stimulus context-dependent fashion. These pop-out effects appeared to originate from area V1, where the strongest responses to pop-out displays were found. The effects of pop-out on competitive interactions among multiple stimuli appeared to operate in an automatic fashion, thus independently of attentional top-down control. Taken together, the studies reviewed in this section

indicate that both top-down attention and bottom-up stimulus-driven mechanisms are critical in resolving competitive interactions among multiple stimuli at intermediate processing levels of visual cortex, thereby filtering out unwanted information from cluttered visual scenes.

COMPETITION CAN BE BIASED BY NONSPATIAL FEEDBACK

The findings just summarized support the proposal that competitive neural circuits can be biased by spatially selective feedback signals. As illustrated in Figure 46.13, feature-selective feedback can also bias competition. Responses of neurons in area TE were recorded as monkeys searched for a target (Chelazzi, Duncan, Miller, & Desimone, 1998). On each trial, the monkey viewed a cue stimulus that appeared at the fixation point. After a delay, an array of stimuli (the search array) appeared within the receptive fields of neurons in area TE. The monkey's task was to indicate whether a target matching the cue stimulus was present in the array, by making a saccade to the target. Locations of the stimuli were selected at random so that the monkey could not know where the target would appear, if it appeared at all. During the delay period, many TE neurons had a higher baseline firing rate when the cue stimulus was a preferred stimulus for the cell than when it was a poor stimulus; that is, neurons that were tuned to respond to the target were activated while the monkey prepared to search for the target. An interesting possibility is that this activation might bias the visual system toward detecting the target object, just as spatially specific feedback is thought to bias the system toward a particular location. Consistent with this, within 150 to 200 ms after the search array appeared, the response of the neuron increased or decreased, depending on whether the target was, respectively, a preferred or a poor stimulus for the cell. That is, shortly after the appearance of the search array, the activity of the cell reflected the identity of the target stimulus and was no longer influenced by the nontarget stimulus, even though the nontarget stimulus was still present physically within its receptive field.

Biases in the form of nonspatial feedback are potent mechanisms to overcome the clutter imposed by natural environments. For example, when we search for objects in the real world, we may form concrete (e.g., looking for a familiar face in a crowd of people) or more abstract (e.g., looking for cars when crossing the street) search templates that facilitate the detection of the behaviorally relevant information that helps to filter out the distracting clutter. Recent studies on attentional selection from natural scenes have shown that the representation of objects in visual cortex is entirely task-dependent (Peelen et al., 2009). Subjects were asked to look for people or cars in a large set of briefly presented natural scenes. Task-relevant

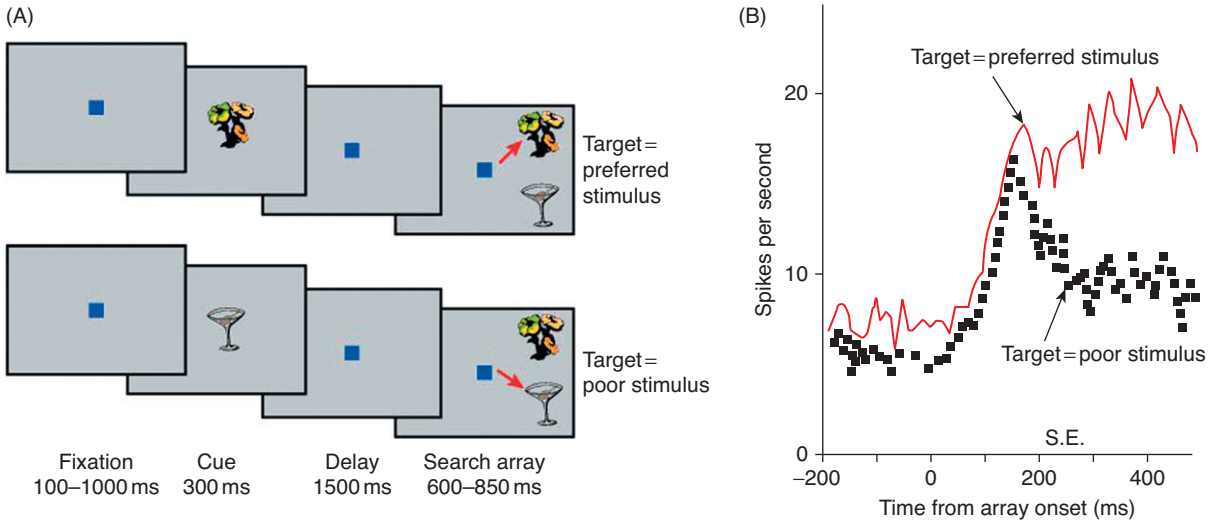

FIGURE 46.13 Responses of inferior temporal (IT) neurons during a memory-guided visual search. (A) Task. Monkeys fixated a spot on a computer screen and were shown a central cue (here, either the flower or the cup). After a delay, two (or more) stimuli appeared within the receptive field and the monkey had to saccade to the stimulus that had appeared earlier as the cue. Sometimes (top four images), the cue was a preferred stimulus for the cell (the flower) and the monkey had to saccade to the preferred stimulus. On separate trials (lower four images), the cue was a poor stimulus (the cup) and the monkey had to saccade to the poor stimulus. (B) Neuronal responses. During the delay period, IT neurons showed an elevated baseline activity that reflected the cue stored in memory. The spontaneous firing rate was higher on trials in which the cue was a preferred stimulus for the cell, relative to trials when the cue was a poor stimulus. After the search array appeared, the responses separated, increasing or decreasing depending on whether the cue was, respectively, a preferred or poor stimulus for the cell. This separation occurred well before the onset of the saccade, which is indicated by the vertical bar on the horizontal axis.

objects were represented in visual cortex, even at spatially unattended locations, while distracter objects did not get processed up to category level, even when spatially attended. Search templates for the target category were shown to pre-activate object-selective cortex in category-specific ways. The strength of preactivation could be used as a reliable predictor of task performance during the detection task. More generally, internally generated templates may provide powerful biases in generating predictions about sensory and behavioral context that enable flexible behavior.

CONCLUSIONS

The behavioral manifestations of attention are clearly not the result of operations in any one dedicated neural center. Selective attention affects neural activity at all levels of the visual system and other sensory systems, with the possible exception of neurons in the sensory periphery. A few structures located at the top of the visual system hierarchy in the parietal, frontal, and cingulate cortices are thought to be relatively more specialized for generating the signals that guide selective attention. These are among the areas that are thought to provide feedback signals that influence sensory processing in areas that are specialized for analyzing the physical properties of the sensory environment.

Answers are beginning to be available to the question of why attention is necessary in the first place. A possible computational bottleneck may be built into all levels of the visual system in the form of spatial receptive fields. The fact that several objects within a certain spatial region can activate the same neuron reduces the ability of such neurons to transmit accurate information about each one of these objects. Automatic gain control mechanisms appear to have been co-opted by the attentional system to mediate selection of attended stimuli from among task-irrelevant distracters. Other bottlenecks will doubtlessly be revealed in future research.

Learning and Memory: Basic Mechanisms

Significant advances have been made in understanding the ways in which the nervous system encodes and retrieves information. One focus of current research is on the understanding of learning and memory at the cellular level, where the information-encoding process can be traced to changes in neuronal properties such as membrane excitability and synaptic strength. One emerging principle is that no single universal mechanism for learning and memory exists. Instead, different memory systems (see Chapter 48) can use different mechanisms. Therefore, a comprehensive understanding of memory mechanisms requires an understanding of the general ways in which neurons are changed by learning and the ways in which those changes are maintained and expressed at the cellular level.

Research during the past several decades on several vertebrate and invertebrate model systems has led to the development of several general principles. A list of these principles (Byrne, 1987) might include the following:

1. Multiple memory systems are present in the brain (see also Chapter 48).
2. Short-term and long-term forms of learning and memory involve changes in existing neural circuits.
3. These changes may involve multiple cellular mechanisms within individual neurons.
4. Second-messenger systems play a role in mediating cellular changes.
5. Changes in membrane channels are often correlated with learning and memory.
6. Long-term memory requires new protein synthesis, whereas short-term memory does not.

This chapter describes several types of neural and molecular mechanisms implicated in learning and memory. The chapter first considers some of the paradigms that have been used to study simple forms of nonassociative and associative learning and provides an example of mechanistic analyses that have been performed in a selected invertebrate model system. The later sections of the chapter describe the mechanisms of two phenomena, which are known as long-term potentiation (LTP) and long-term depression (LTD). Both LTP and LTD occur in forebrain structures, and LTP and LTD are thought to be mechanisms for memory storage in the central nervous system.

PARADIGMS HAVE BEEN DEVELOPED TO STUDY ASSOCIATIVE AND NONASSOCIATIVE LEARNING

Associative Learning

Associative learning is a broad category that includes many of our daily learning activities that involve the formation of associations among stimuli and/or responses. It is usually subdivided into classical conditioning and instrumental conditioning. Classical (or Pavlovian) conditioning is induced by a procedure in which a generally neutral stimulus, termed a *conditioned stimulus* (CS), is paired with a stimulus that generally elicits a response, termed an *unconditioned stimulus* (US). Two examples of unconditioned stimuli are food, which elicits salivation, or a shock to the foot, which elicits limb withdrawal. Instrumental (or operant) conditioning is a process by which an organism learns to associate consequences with its own behavior. The delivery of a reinforcing stimulus is contingent upon the expression of a designated behavior. The probability that this behavior will be expressed

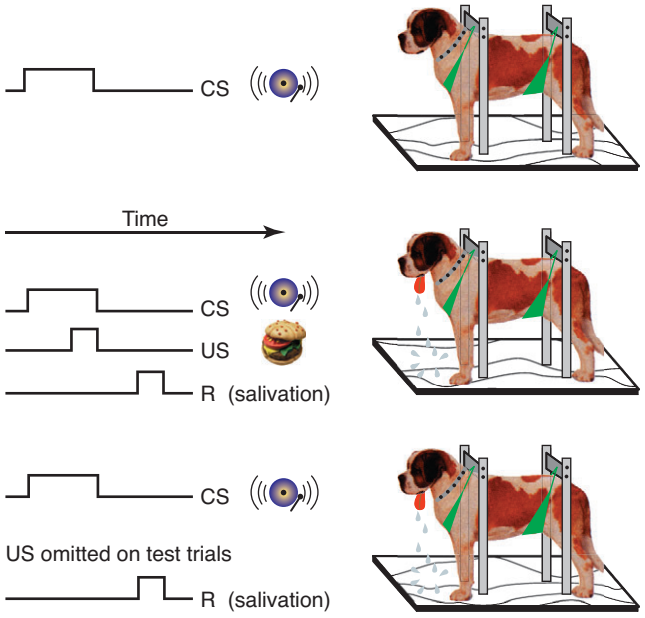

FIGURE 47.1 Classical conditioning. In the procedure introduced by Pavlov, the production of saliva is monitored continuously. Presentation of meat powder (US) reliably leads to salivation, whereas some "neutral" stimulus such as a bell (CS) initially does not. With repeated pairings of the bell and meat powder, the animal learns that the bell predicts the food and salivates in response to the bell alone. *Modified from Rachlin (1991).*

is then altered. This chapter focuses on classical conditioning, as it is mechanistically the best understood type of associative conditioning.

An astute observation by Ivan Pavlov, a Russian physiologist who had been studying digestion in dogs, led to his discovery of classical conditioning. He first noticed that the mere sight of the food dish caused dogs to salivate. He continued the experiments to see if dogs would also salivate in response to a bell rung at feeding time. Pavlov trained dogs to stand in a harness and, after the sound of a bell, fed them meat powder (Fig. 47.1). At first, the bell by itself did not elicit any response, but the meat powder elicited reflex salivation, which was termed the *unconditioned response* (UR). He noted that after a few pairings of the bell and meat powder the dogs began to salivate when the bell rang, before they received the meat powder. This response is termed the *conditioned response* (CR). This type of conditioning came to be called reward or appetitive *classical conditioning*. If the bell or another stimulus was followed by an unpleasant event, such as an electric shock, then a variety of autonomic responses became conditioned. This type of conditioning is termed aversive conditioning.

Nonassociative Learning

Three examples of nonassociative learning have received the most experimental attention: habituation, dishabituation, and sensitization. *Habituation* is defined as a reduction in the response to a stimulus that is delivered repeatedly. *Dishabituation* refers to the restoration or recovery of a habituated response due to the presentation of another, typically strong, stimulus to the animal. *Sensitization* is an enhancement or augmentation of a response produced by the presentation of a strong stimulus. The following sections focus on the neural and molecular mechanisms of sensitization.

INVERTEBRATE STUDIES: KEY INSIGHTS FROM *APLYSIA* INTO BASIC MECHANISMS OF LEARNING

Since the mid-1960s, the marine mollusc *Aplysia* has proven to be an extremely useful model system to gain insights into the neural and molecular mechanisms of simple forms of memory. Indeed, the pioneering discoveries of Eric Kandel using this animal were recognized by his receipt of the Nobel Prize in Physiology or Medicine in 2000. A number of characteristics make *Aplysia* well suited for the examination of the molecular, cellular, morphological, and network mechanisms underlying neuronal modifications (plasticity) and learning and memory. The animal has a relatively simple nervous system with large, individually identifiable neurons that are accessible for detailed analyses. Indeed, the neurons and neural circuits that mediate many behaviors in *Aplysia* have been identified. In several cases, these behaviors have been shown to be modifiable by learning. Moreover, specific loci within neural circuits at which modifications occur during learning have been identified, and aspects of the cellular mechanisms underlying these modifications have been analyzed (For reviews see Bailey & Kandel, 2008; Byrne & Kandel, 1996; Fioravante, Antzoulatos, & Byrne, 2008; Kandel, 2001).

Sensitization of withdrawal reflexes has been particularly well studied. A single sensitizing stimulus, such as a brief several second-duration electric shock, can produce a reflex enhancement that lasts minutes (short-term sensitization), whereas prolonged training (e.g., multiple stimuli over an hour or more) produces an enhancement that lasts from days to weeks (long-term sensitization).

Multiple Cellular Processes Mediate Short- and Long-Term Sensitization in *Aplysia*

A discussion of memory mechanisms can be divided into three parts: induction, expression, and maintenance. *Induction* refers to the initial events that trigger or initiate the modification process; *expression* concerns how the modification process is ultimately expressed; and *maintenance* addresses the manner in which the modification is made to endure over time.

Short-Term Sensitization

Short-term (minutes) sensitization is induced when a single, brief train of shocks is delivered to the body wall of the animal. This process results in the release of modulatory transmitters, such as serotonin (5-HT), from a distinct class of interneurons (IN) referred to as facilitatory neurons (Fig. 47.2A1). These facilitatory neurons regulate the properties of the sensory neurons (SN) and the strength of their connections with postsynaptic interneurons and motor neurons (MN) through a process called *heterosynaptic facilitation* (Byrne & Kandel, 1996; Figs. 47.2A2 and 47.2A3). The molecular mechanisms contributing to short-term heterosynaptic facilitation are illustrated in Figure 47.2B. Serotonin binds to multiple types of G-protein-coupled receptors localized in the membrane of SNs and activation of these receptors recruits at least two predominant signaling cascades in the SNs: the cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) and the diacylglycerol/protein kinase C (DAG/PKC) cascades (Byrne & Kandel, 1996). Calcium/calmodulin-dependent protein kinase (CaM kinase II) appears to be engaged as well. PKA and PKC have multiple targets, including membrane ion channels, thus affecting the spike waveform and the excitability of the SN. For example, activation of the PKA and PKC cascades modifies various K^+ channels, leading to an enhanced spike activity (i.e., enhanced excitability), and broadening of the action potential. Reflections of enhanced excitability include an increase in the number of action potentials elicited in a sensory neuron by a fixed extrinsic current injected into the cell or by a fixed stimulus to the skin (Fig. 47.2A3). Spike broadening leads to enhanced Ca^{2+} influx in presynaptic terminals and facilitates transmitter release. In addition to spike broadening, spike-duration-independent mechanisms of enhanced transmitter release have been implicated in 5-HT-induced heterosynaptic facilitation. These mechanisms involve direct modulation of a presynaptic calcium conductance independently of spike broadening (Leal & Klein, 2009) as well as an increase in the number of transmitter-containing synaptic vesicles that become available for release, possibly through synapsin-regulated vesicle mobilization (Fig. 47.2; Byrne & Kandel, 1996; Fioravante, Liu, Netek, Cleary, & Byrne, 2007; Zhao & Klein, 2002). This process is represented in Figure 47.2B (large open arrow) as the translocation or mobilization of transmitter vesicles from a reserve pool to a releasable pool results in an increase in the number of transmitter-containing vesicles available for release, with subsequent action potentials in the sensory neuron. The maintenance of short-term sensitization is dependent on the persistence of the PKA- and PKC-induced phosphorylations of the various substrate proteins. Prolonged treatments of 5-HT (1.5 h) also activate mitogen-activated protein kinase (MAPK) (for review, see Sharma & Carew, 2004). However, this pathway appears to be important only for the induction of longer-term processes (see section on Long-term Sensitization).

The consequences of activating these multiple second-messenger systems and modulating these various cellular processes are expressed when test stimuli elicit action potentials in the sensory neuron at various times after the presentation of the sensitizing stimuli (Fig. 47.2A3).

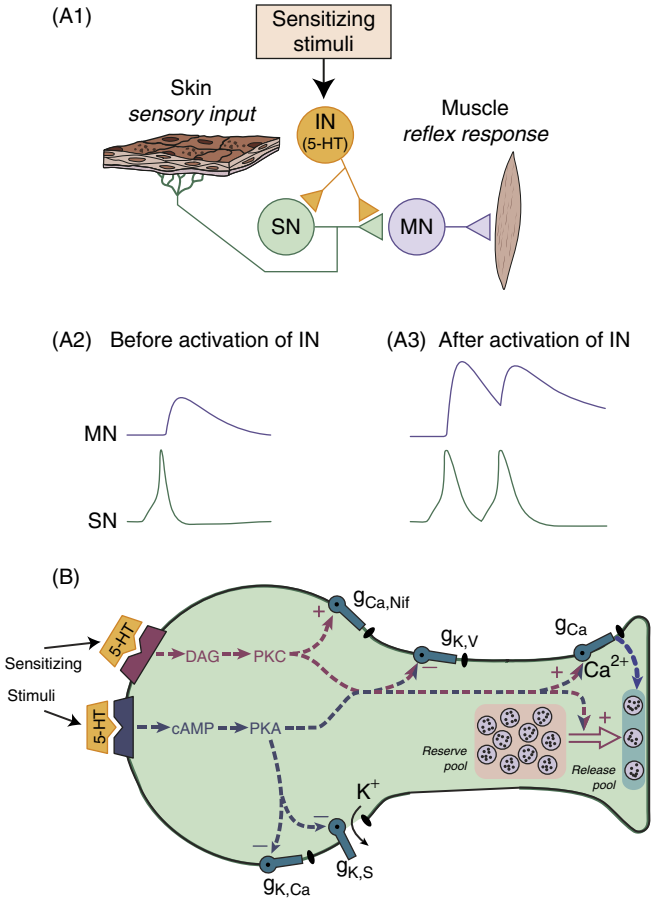

FIGURE 47.2 Model of short-term heterosynaptic facilitation of the sensorimotor connection that contributes to short-term sensitization in *Aplysia*. (A1) Sensitizing stimuli activate facilitatory interneurons (IN) that release modulatory transmitters, one of which is 5-HT. The modulator leads to an alteration of the properties of the sensory neuron (SN). (A2 and A3) The enhanced synaptic input to the motor neuron (MN) (A3) results from enhanced sensory input, partly due to two mechanisms. First, the same peripheral stimulus can evoke a greater number of action potentials in the presynaptic SN (i.e., enhanced excitability). Second, each action potential fired by an SN produces a stronger synaptic response in the MN (i.e., synaptic facilitation). (B) Model of a SN that depicts the multiple processes for short-term facilitation and changes in excitability that contribute to short-term sensitization. 5-HT released from facilitatory neurons binds to at least two distinct classes of receptors on the outer surface of the membrane and leads to the transient activation of two intracellular second messengers, DAG and cAMP, and their respective kinases (PKC and PKA). These kinases affect multiple cellular processes, the combined effects of which lead to changes in excitability and enhanced transmitter release when subsequent action potentials are fired in the sensory neuron (see text for additional details). *Modified from Byrne and Kandel (1996).*

More transmitter is available for release as a result of the mobilization process and each action potential results in a larger influx of Ca^{2+} to trigger release of the available transmitter. This facilitation of transmitter release from the sensory neuron leads to a larger postsynaptic potential in the motor neuron. Larger postsynaptic potentials lead to enhanced activation of interneurons and motor neurons and thus to an enhanced behavioral response.

Of general significance is the observation that a single modulatory transmitter (i.e., 5-HT) activates multiple kinase systems. The involvement of multiple second messenger systems in synaptic plasticity also appears to be a theme emerging from mammalian studies. For example, as discussed in a later section of the chapter, the induction of LTP in the CA1 area of the hippocampus appears to involve MAPK, PKC, CaM kinase II , and tyrosine kinase (reviewed in Dineley et al., 2001; Miyamoto, 2006).

Long-Term Sensitization

Sensitization also exists in a long-term form, which persists for at least 24 h. Whereas short-term sensitization can be produced by a single brief stimulus, the induction of long-term sensitization requires a more extensive training period over an hour or more.

Both short- and long-term sensitization share some common cellular pathways during their *induction.* For example, both forms activate the cAMP/PKA cascade (Fig. 47.3). However, in the long-term form, unlike the short-term form, activation of the cAMP/PKA cascade induces gene transcription and new protein synthesis (Kandel, 2001; Fioravante et al., 2008). Repeated training leads to a translocation of PKA to the nucleus, where it phosphorylates the transcriptional activator CREB1 (cAMP responsive element binding protein1). CREB1 binds to a regulatory region of genes known as a CRE (cAMP responsive element). Whereas CREB1 acts as an *activator* of gene transcription, a related transcription factor, CREB2, acts constitutively as a *repressor* of gene transcription. This repression of transcription is in turn *suppressed* by MAPK phosphorylation of CREB2 (Guan et al., 2002). MAPK is activated by multiple pathways including a 5-HT sensitive tyrosine receptor kinase-like molecule (ApTrk), and through feedback pathways involving the peptide sensorin and transforming growth factor β (TGF-β) (see following).

The role of transcription factors in long-term memory formation is not limited to the induction phase but may also extend to the consolidation phase, where consolidation is defined as the time window during which RNA and protein synthesis are required for converting short- to long-term memory. For example, treatment of ganglia with 5 pulses of 5-HT over a 1.5 h period to mimic sensitization training leads to the binding of CREB1 to the promoter of its own gene and induces CREB1 synthesis. The necessity of prolonged transcription and translation for long-term facilitation (LTF) observed 24 h after treatment persists for at least 10 h after induction. These results suggest that CREB1 can regulate its own level of expression, giving rise to a CREB1 positive feedback loop that supports memory consolidation (Liu, Cleary, & Byrne, 2011).

The combined effects of activation of CREB1 and removal of CREB2's repression of transcription lead to changes in the synthesis of specific proteins. So far, more

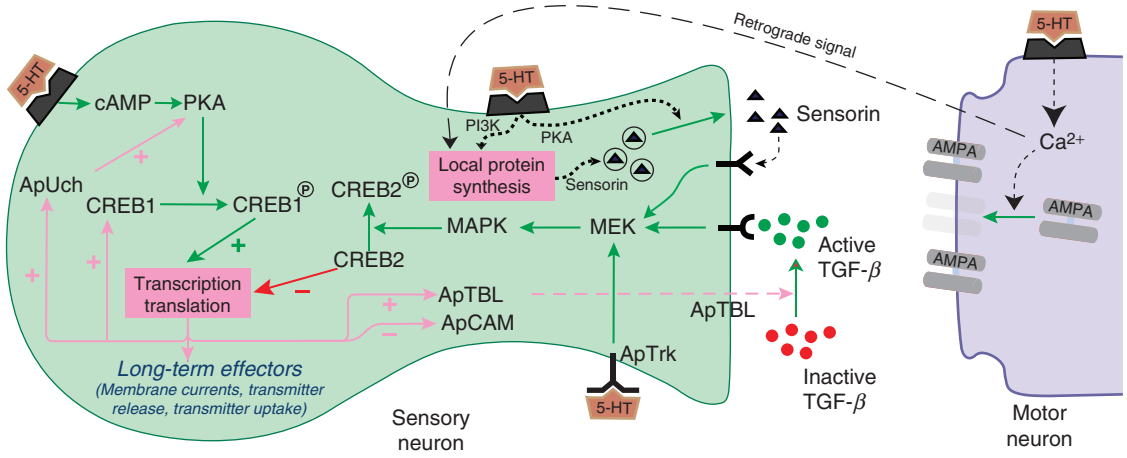

FIGURE 47.3 Simplified scheme of the mechanisms in SNs that contribute to long-term sensitization. Sensitization training leads to cAMP-dependent regulation of CREB1. Serotonin also leads to activation of MAPK, which regulates CREB2. Whereas CREB1 acts as an initiator of gene transcription, CREB2 acts as a repressor of gene transcription. The combined effects of activation of CREB1 and suppression of CREB2 lead to regulation of the synthesis of at least 10 proteins, only some of which are shown. ApTBL is believed to activate latent forms of TGF-β, which can then bind to receptors on the SN. TGF-β activates MAPK, which may act by initiating a second round of gene regulation by affecting CREB2-dependent pathways. Serotonin can also increase the release of the peptide sensorin, which binds to autoreceptors leading to further activation of MAPK. Increased local synthesis and subsequent release of sensorin can also be evoked by 5-HT, through the PI3 kinase and type II PKA, respectively. Because increased synthesis of sensorin requires elevation of postsynaptic calcium, a retrograde signal is also postulated. In addition to the retrograde signal, 5-HT-induced postsynaptic signaling also leads to an increased number of glutamate receptors.

than 10 gene products that are regulated by sensitization training have been identified, and others are likely to be found in the future. These results indicate that there is not a single memory gene or protein, but that multiple genes are regulated, and they act in a coordinated way to alter neuronal properties and synaptic strength. The following section discusses several regulated proteins of particular significance.

The downregulation of a homologue of a neuronal cell adhesion molecule (NCAM), denoted ApCAM, plays a key role in long-term facilitation. This downregulation has two components. First, the synthesis of ApCAM is reduced. Second, preexisting ApCAM is internalized via increased endocytosis. The internalization and degradation of ApCAM allow for the restructuring of the axon arbor (Bailey & Kandel, 2008). The SN can now form additional connections with the same postsynaptic target or make new connections with other cells. In addition, the presynaptic cell-adhesion protein neurexin, along with its postsynaptic counterpart neuroligin and their transsynaptic interaction, are required for 5-HT-induced LTF and the associated presynaptic structural changes (Choi et al., 2011). Furthermore, the stabilization of new structures depends on a translation-regulating protein, the *Aplysia* homolog of cytoplasmic polyadenylation element-binding protein (ApCPEB; Miniaci et al., 2008). ApCPEB appears to have prion-like properties in that it can appear in one of two or more conformations, one of which dominates and allows ApCPEB to self-perpetuate. Conversion of ApCPEB to the self-perpetuating state is enhanced by 5-HT and required for the persistence of LTF (Si, Kandel, Majumdar, Grindley, & Choi, 2010). Finally, it has been suggested that persistence of long-term facilitation and sensitization can be disrupted by inhibition of an *Aplysia* homolog of the protein kinase M (PKM Apl III; Cai, Pearce, Chen, & Glanzman, 2011). PKM (PKMζ) is a constitutively active PKC isoform that phosphorylates vertebrate AMPA-type glutamate receptors and enhances their responses, thus supporting the persistence of long-term potentiation of synapses (Sacktor, 2011).

Another protein whose synthesis is regulated by long-term facilitation is *Aplysia* tolloid/BMP-like protein (ApTBL-1). Tolloid and the related molecule BMP-1 appear to function as secreted Zn^{2+} proteases. In some systems, they activate members of the transforming growth factor β (TGF-β) family. Indeed, in SNs, TGF-β mimics the effects of 5-HT in that it produces long-term increases in the synaptic strength of the SNs (Zhang, Endo, Cleary, Eskin, & Byrne, 1997). Interestingly, TGF-β activates MAPK in the SNSs and induces its translocation to the nucleus. Thus, TGF-β could be part of an *extracellular* positive feedback loop, possibly leading to another round of protein synthesis (Fig. 47.3) to further consolidate the memory (Zhang, Endo, Cleary, Eskin, & Byrne, 1997). Another extracellular positive feedback loop involves the 5-HT-induced regulation of the release of the SN-specific neuropeptide sensorin (Fig. 47.3). Synthesis of sensorin is stimulated by 5-HT in a PI3 kinase (Phosphatidylinositol 3-kinase)-dependent manner and somewhat surprisingly, requires elevation of postsynaptic calcium (Cai, Chen, & Glanzman, 2008; Hu, Wu, & Schacher, 2006). The mechanism through which postsynaptic calcium regulates presynaptic local protein synthesis of sensorin remains unclear, but the release of a retrograde signal has been postulated (Cai et al., 2008). Interestingly, although the existence of a postsynaptic neuron seems to be required for long-term facilitation, it is not required for another correlate of long-term sensitization, increased SN excitability (Cleary, Lee, & Byrne, 1998; Liu et al., 2011). Sensorin binding to presynaptic autoreceptors activates MAPK (Hu et al., 2006), which phosphorylates CREB2 and contributes to transcriptional regulation during the consolidation of LTF.

Another important protein, *Aplysia* ubiquitin hydrolase (ApUch), appears to be involved in an *intracellular* positive feedback loop. During the induction of long-term facilitation, ApUch levels in SNs are increased, possibly via CREB phosphorylation and a consequent increase in *ApUch* transcription. The increased levels of ApUch increase the rate of degradation of proteins, via the ubiquitin-proteosome pathway, including the regulatory subunit of PKA (Chain et al., 1999). The catalytic subunit of PKA, when freed from the regulatory subunit, is highly active. Thus, increased ApUch will lead to an increase in PKA activity and a more protracted phosphorylation of CREB1. This phosphorylated CREB1 may act to further prolong *ApUch* expression, thus closing a positive feedback loop. Protein degradation, in general, and the role of ubiquitination in particular, is an emerging theme in recent studies on the neural basis of long-term memory (Fioravante & Byrne, 2011).

One simplifying hypothesis is that the mechanisms underlying the *expression* of short- and long-term sensitization are the same, but extended in time for long-term sensitization. Some evidence supports this hypothesis. For example, long-term sensitization, like short-term sensitization, is associated with an enhancement of sensorimotor connections. In addition, K^+ currents and the excitability of sensory neurons are modified by long-term sensitization (Cleary et al., 1998). However, the mechanisms underlying the *expression* of short- and long-term sensitization differ in four fundamental ways. First, long-term sensitization training leads to a decrease in the duration of the SNs action potential (Antzoulatos & Byrne, 2007). Second, structural changes such as neurite outgrowth and active zone remodeling are associated with the expression of long-term but not with short-term sensitization (Bailey & Kandel, 2008). Interestingly, the structural changes take time to develop. Long-term synaptic facilitation

measured one day after four days of training is associated with structural changes, whereas long-term facilitation measured one day after a single training session is not (Wainwright, Byrne, & Cleary, 2004). Third, long-term sensitization is associated with an increase in high-affinity glutamate uptake (Levenson et al., 2000). A change in glutamate uptake could potentially exert a significant effect on synaptic efficacy by regulating the amount of transmitter available for release, the rate of clearance from the cleft, and thereby the duration of the excitatory postsynaptic potential (EPSP) and the degree of receptor desensitization. Finally, long-term sensitization has been correlated with changes in the postsynaptic cell (i.e., the motor neuron; Cleary et al., 1998). Thus, as with other examples of memory, multiple sites of plasticity exist even within this simple reflex system.

Other Temporal Domains for the Memory of Sensitization

Historically, memory has been divided into two temporal domains, short term and long term. It has become increasing clear from studies of a number of memory systems that this distinction is overly simplistic. For example, in *Aplysia*, Carew and colleagues (Sutton, Masters, Bagnall, & Carew, 2001) and Kandel and colleagues (Ghirardi, Montarolo, & Kandel, 1995) have discovered an intermediate phase of memory that has distinctive temporal characteristics and a unique molecular signature. The intermediate-phase memory for sensitization is expressed at times approximately 5 min to 3 h after the beginning of training. Like long-term sensitization, its induction requires protein synthesis. Intermediate-term sensitization relies on both presynaptic and postsynaptic translation (protein synthesis; Antonov, Kandel, & Hawkins, 2010; Jin, Kandel, & Hawkins, 2011; Villareal, Li, Cai, & Glanzman, 2007), but not on transcription (mRNA synthesis). Intermediate-term synaptic facilitation, induced by 5-HT, requires activity of presynaptic PKC and postsynaptic CaM kinase II (Jin et al., 2011). In contrast to the well-established role of presynaptic PKA in short-term facilitation, its role in intermediate-term facilitation appears to be more variable, depending on the training protocol (Antonov et al., 2010; Ghirardi et al., 1995; Jin et al., 2011). Finally, intermediate-term facilitation has been correlated with activation of previously "silent" release sites by the recruitment of synaptic vesicles to preexisting varicosities (Kim et al., 2003).

In addition to intermediate-term memory, it is likely that *Aplysia* has different phases of long-term memory. For example, increased synthesis of a number of proteins occurs at 24 h after sensitization training and some of these proteins are different from those whose synthesis is increased during and immediately after training. These results suggest that the memory for sensitization that persists for times greater than 24 h may be dependent on the synthesis of proteins occurring at 24 h and may have a different molecular signature than the 24-h memory.

Mechanisms Underlying Associative Learning of Withdrawal Reflexes in *Aplysia*

In addition to sensitization, the withdrawal reflexes of *Aplysia* are subject to classical conditioning. The short-term classical conditioning observed at the behavioral level reflects, at least in part, a cellular mechanism called *activity-dependent neuromodulation* (Hawkins, Abrams, Carew, & Kandel, 1983; Walters & Byrne, 1983). A diagram of the general scheme is presented in Figure 47.4. The US pathway is activated by a shock to the animal, which elicits a withdrawal response (the UR). When a CS is paired consistently with the US, the animal will develop a withdrawal response (CR) to the CS. Activity-dependent neuromodulation is proposed as the mechanism for this pairing-specific effect. The US activates both a motor neuron (UR) and a modulatory system. The modulatory system delivers 5-HT to all the SNs (parts of the various CS pathways), which leads to a nonspecific enhancement of transmitter release from the SNs. This nonspecific enhancement contributes to short-term sensitization (see prior discussion). SNs whose activity is temporally contiguous with the US-mediated reinforcement are additionally modulated. Spiking in a SN during the presence of 5-HT leads to changes in that cell relative to other SNs whose activity was not paired with the US. Thus, a subsequent CS will lead to an enhanced activation of the reflex (Fig. 47.4B). Figure 47.5 illustrates a more detailed model of the proposed cellular mechanisms responsible for this example of classical conditioning. The modulator (US) acts by increasing the activity of adenylyl cyclase (AC), which in turn increases the levels of cAMP. Paired spiking in the SNs (CS) leads to a simultaneous increase in the level of intracellular calcium, which acting through calmodulin (CaM) greatly enhances the action of the modulator to increase AC activity and cAMP production. Thus, this system determines CS–US contiguity by a method of coincidence detection at the presynaptic terminal.

Now, consider the postsynaptic side of the synapse. The postsynaptic region contains NMDA-type receptors (see Chapters 8 and 10). These receptors need concurrent delivery of glutamate and depolarization in order to allow calcium to enter. The glutamate is provided by the activated SN (CS), and the depolarization is provided by the US (Antonov, Antonova, Kandel, & Hawkins, 2003; Roberts & Glanzman, 2003). Thus, the postsynaptic neuron provides another example of coincidence detection. The increase in intracellular calcium putatively causes a retrograde signal to be released from the postsynaptic cell to the presynaptic terminal, ultimately acting to further enhance the cAMP cascade in the SN. The overall amplification of the cAMP cascade acts to raise the level of PKA,

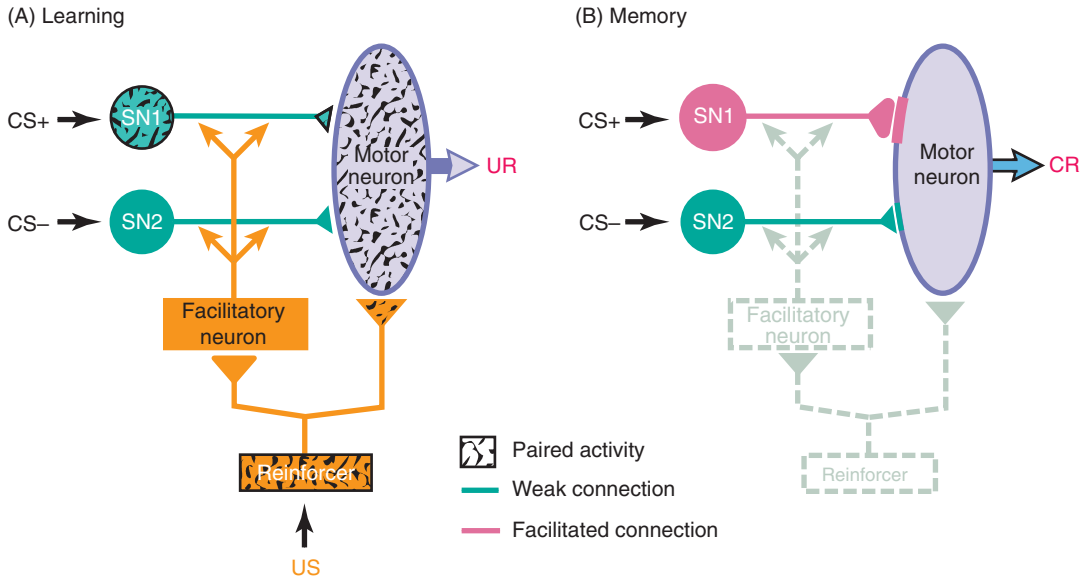

FIGURE 47.4 Model of classical conditioning of a withdrawal reflex in *Aplysia*. (A) Activity in a sensory neuron (SN1) along the CS+ (paired) pathway is coincident with activity in neurons along the reinforcement pathway (US). However, activity in the sensory neuron (SN2) along the CS– (unpaired) pathway is not coincident with activity in neurons along the US pathway. The US directly activates the motor neuron, producing the UR. The US also activates a modulatory system in the form of the facilitatory neuron, resulting in the delivery of a neuromodulatory transmitter to the two sensory neurons. The pairing of activity in SN1 with the delivery of the neuromodulator yields the associative modifications. (B) After the paired activity in A, the synapse from SN1 to the motor neuron is selectively enhanced. Thus, it is more likely to activate the motor neuron and produce the conditioned response (CR) in the absence of US input. *Modified from Lechner and Byrne (1998).*

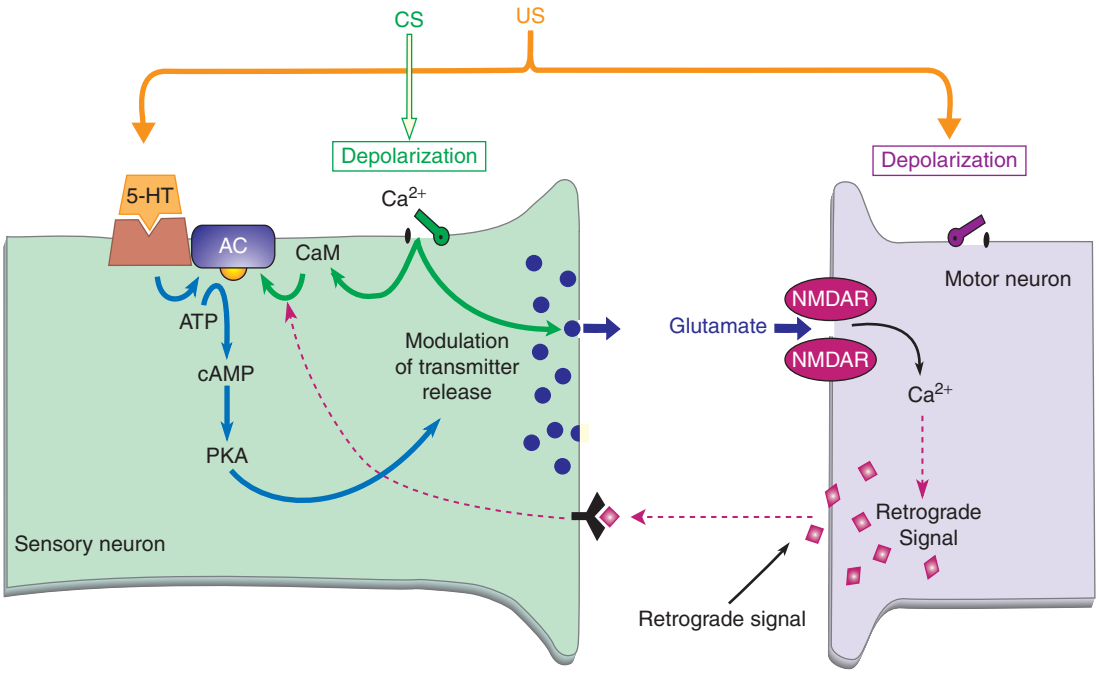

FIGURE 47.5 Model of associative facilitation at the *Aplysia* sensorimotor synapse. This model has both a presynaptic and a postsynaptic detector for the coincidence of the CS and the US. Furthermore, a putative retrograde signal allows for the integration of these two detection systems at the presynaptic level. The CS leads to activity in the sensory neuron, yielding presynaptic calcium influx, which enhances the US-induced cAMP cascade. The CS also induces glutamate release, which results in postsynaptic calcium influx through NMDA receptors if the glutamate release is paired with the US-induced depolarization of the postsynaptic neuron. The postsynaptic calcium influx putatively induces a retrograde signal, which further enhances the presynaptic cAMP cascade. The end result of the cAMP cascade is to modulate transmitter release and enhance the strength of the synapse. *Modified from Lechner and Byrne (1998).*

which in turn leads to the modulation of transmitter release. These activity-dependent changes enhance synaptic efficacy between the specific SN of the CS pathway and the motor neuron. Thus, the SN along the CS pathway will be better able to activate the motor neuron and produce the CR.

Summary

Certain invertebrates display an enormous capacity for learning and offer particular experimental advantages for analyzing the cellular and molecular mechanisms of learning. For example, behaviors in *Aplysia* are mediated by relatively simple neural circuits, which can be analyzed with conventional anatomical and electrophysiological approaches. Once the circuit is specified, the neural locus for the particular example of learning can be found, and biophysical, biochemical, and molecular approaches can then be used to identify mechanisms underlying the change. The relatively large size of some of these cells allows these analyses to take place at the level of individually identified neurons. Individual neurons can be removed surgically and assayed for changes in the levels of second messengers, protein phosphorylation, RNA, and protein syntheses. Moreover, peptides and nucleotides can be injected into individual neurons. This chapter has focused exclusively on *Aplysia,* but many other invertebrates have proven to be valuable model systems for the cellular and molecular analysis of learning and memory. Each has its own unique advantages.

Other invertebrate model systems such as *Drosophila,* although not ideal for cell biological approaches because of their small neurons, offer tremendous advantages for obtaining insights into mechanisms of learning and memory through the application of genetic approaches. A frequently used protocol in *Drosophila* employs a two-stage differential odor–shock avoidance procedure, in which animals learn to avoid odors paired (CS+) with shock but not odors explicitly unpaired (CS–). This learning is typically retained for 4–6 h, but retention for 24 h to 1 week can be produced by a spaced training procedure. Several mutants deficient in learning have been identified. Analysis of the affected genes has revealed elements of the cAMP signaling pathway as key in learning and memory. It is now known that in *Drosophila* as in *Aplysia*, the formation of long-term memory requires activation of the cAMP signaling pathway, which, in turn, activates members of the CREB transcription family. These proteins appear to be the key molecular switch that enables expression of genes necessary for the formation of long-term memories. These transcription factors are also important for long-term memory in vertebrates (see following). See Byrne (1987) and Carew (2000) for a review of other selected invertebrate model systems that have contributed importantly to the understanding of memory mechanisms.

VERTEBRATE STUDIES: LONG-TERM POTENTIATION

In contrast to the studies on invertebrates like *Aplysia* described earlier, it has been more difficult to link synaptic plasticity with specific examples of learning in vertebrates. However, one exciting and extensively studied candidate memory mechanism is the synaptic phenomenon termed long-term potentiation (LTP). This phenomenon is defined as a persistent increase in synaptic strength (as measured by the amplitude of the EPSP in a follower neuron) that can be induced rapidly by a brief burst of spike activity in the presynaptic afferents. The intense experimental interest in LTP is driven by the working hypothesis that this form of synaptic plasticity may participate in information storage in several brain regions. This section describes the properties of LTP and how it is studied, reviews its underlying mechanisms, and explores the possibility of linkages between LTP and learning and memory.

Long-Term Potentiation Occurs in a Variety of Neural Synapses

The first evidence that long-term modification of mammalian synapses could be induced by experimental means appeared in 1973, when Timothy Bliss and Terje Lomo demonstrated LTP in the hippocampus of the anesthetized rabbit. Brief, high-frequency stimulation (HFS) of the perforant-pathway input to the dentate gyrus produced a long-lasting enhancement of the extracellularly recorded field potential. Subsequent studies of nonanesthetized animals have shown that LTP can last for weeks or months. Originally thought to be unique to the mammalian hippocampal formation, LTP is now known to occur in the cerebellum, neocortical regions, subcortical regions such as the amygdala, mammalian peripheral nervous system, the arthropod neuromuscular junction, and the *Aplysia* sensorimotor synapse. It is important to bear in mind that no universal mechanism exists for inducing LTP. Indeed, different mechanisms may be used at the same synapse, depending on the experimental conditions. This chapter focuses primarily on the LTP at the synapse made by a pyramidal neuron in the CA3 region of the hippocampus to a pyramidal neuron in the CA1 region of the hippocampus.

Long-Term Potentiation at the CA3–CA1 Synapse

Within the hippocampus proper, by far the best studied synapse is that from the Schaffer collateral/commissural (Sch/com) fibers of the CA3 pyramidal cells to the CA1 pyramidal cells (Fig. 47.6). In fact, this is probably the most commonly studied synapse in the mammalian brain, due in part to its relatively simple circuitry and its laminar organization. These features make it possible to extract

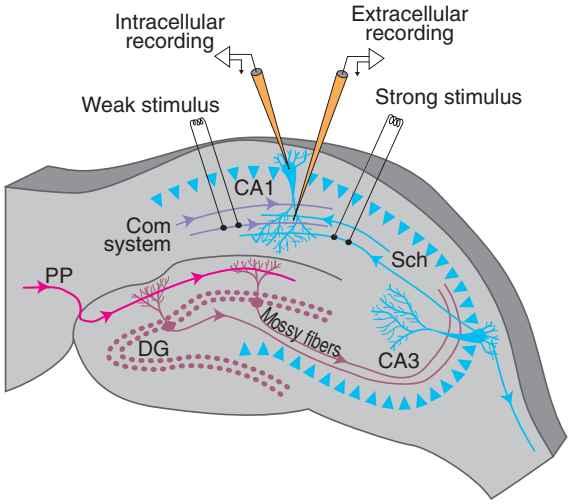

FIGURE 47.6 Schematic of a transverse hippocampal brain slice preparation from the rat. Two extracellular stimulating electrodes are used to activate two nonoverlapping inputs to pyramidal neurons of the CA1 region of the hippocampus. By suitably adjusting the current intensity delivered to the stimulating electrodes, different numbers of Schaffer collateral/commissural (Sch/com) axons can be activated. In this way, one stimulating electrode was made to produce a weak postsynaptic response and the other to produce a strong postsynaptic response. Also illustrated is an extracellular recording electrode placed in the stratum radiatum (the projection zone of the Sch/com inputs) and an intracellular recording electrode in the stratum pyramidale (the cell body layer). Also indicated is the mossy fiber projection from granule cells of the dentate gyrus (DG) to the pyramidal neurons of the CA3 region. *Adapted from Barrionuevo and Brown (1983).*

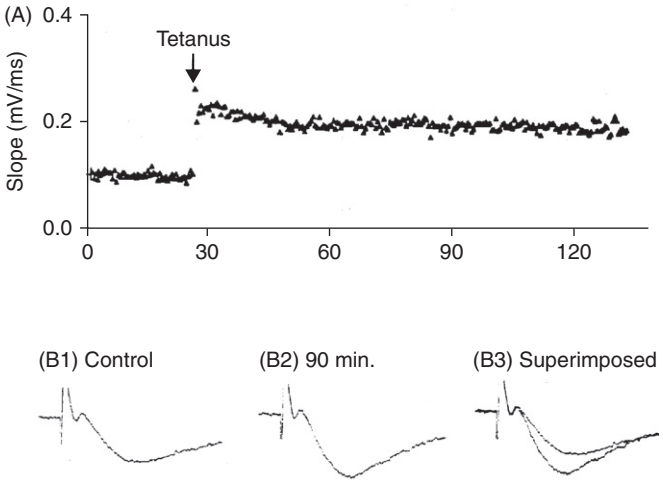

FIGURE 47.7 LTP at the CA3–CA1 synapse in the hippocampus. (A) Test stimuli are delivered repeatedly once every 10 s while the strength of the synaptic connection is monitored. Strength can be assessed by the *amplitude* of the extracellularly recorded EPSP or, as was done in this example, as the *slope* of the rising phase of the EPSP, which provides an accurate reflection of its strength. To induce LTP, two 1 s, 100 Hz tetani were delivered with a 20-s interval. Subsequent test stimuli produce enhanced EPSPs. The enhancement is stable and persists for at least 2 h. Examples of extracellulary recorded field EPSPs before (B1) and 90 min after the induction of LTP (B2). In B3 the traces from B1 and B2 are superimposed. *Modified from Nicoll et al. (1988).*

useful data from extracellular recordings, which are easier to perform than intracellular recordings and preferable for some purposes. Examples of LTP induction are illustrated in Figure 47.7B. The lower waveforms are extracellularly recorded field EPSPs recorded in the CA1 region in response to a single weak stimulation of the Sch/com pathway. Brief electric stimuli delivered to this pathway lead to the initiation of action potentials in the individual axons in the pathway. These action potentials then propagate to the synaptic terminals. The release of transmitter from the multiple afferent terminals produces a summated EPSP in the postsynaptic cell, which can be detected with an extracellular electrode. Test stimuli are delivered repeatedly at a low rate that produces stable EPSPs in the postsynaptic cell (Figs. 47.7A and B1). After a baseline period, a brief high-frequency tetanus is delivered. Subsequent test stimuli produce enhanced EPSPs (Fig. 47.7B2). The enhancement persists for many hours. Although the synaptic enhancement is stable after the tetanus, LTP, like heterosynaptic facilitation of the sensorimotor synapse in *Aplysia*, has multiple temporal domains. One domain is associated with an enhancement of the EPSP that persists for about 90 min. This form of LTP is referred to as early LTP (E-LTP). A second domain referred to as late LTP (L-LTP) is associated with synaptic enhancement that persists for periods of time greater than about 90 min. As described later, different mechanisms underlie the induction and maintenance of E- and L-LTP.

Properties of Long-Term Potentiation at the CA3–CA1 Synapse Include Cooperativity, Associativity, and Input Specificity

The CA3–CA1 synapses exhibit a form of LTP characterized by "classical" properties that have been termed "cooperativity," "associativity," and "input specificity" (Fig. 47.8) (Bliss & Collingridge, 1993; Brown, Ganong, Kairiss, & Keenan, 1990). These "classical properties" are actually different manifestations of the same underlying mechanism that is responsible for this type of LTP. Other less commonly studied types of LTP have different signatures.

Cooperativity refers to the fact that the probability of inducing LTP, or the magnitude of the resulting change, increases with the number of stimulated afferents. Weak HFS, which activates fewer afferents, often fails to induce LTP (Fig. 47.8A). In contrast, strong stimulation, which activates more afferents, produces LTP more reliably (Fig. 47.8B). Thus, the additional axons recruited by higher stimulation intensities "cooperate" to trigger LTP.

Associativity was shown in preparations in which two distinct axonal inputs converged onto the same postsynaptic target. Consider the interactions between two stimulus pathways, one termed the *weak* pathway with a

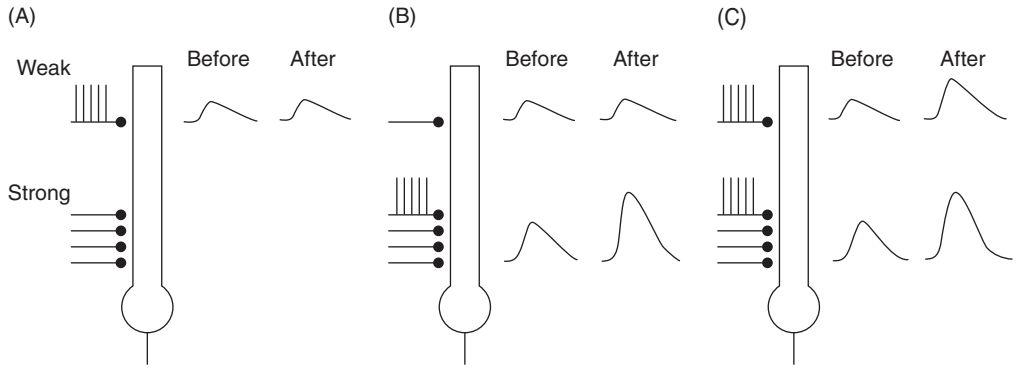

FIGURE 47.8 Features of LTP at CA3–CA1 synapses in the hippocampus. A single hippocampal pyramidal cell is shown receiving a weak and strong synaptic input. (A) Tetanic stimulation of the weak input alone does not cause LTP in that pathway (compare the EPSP before and after the tetanus). (B) Tetanic stimulus of the strong input alone causes LTP in the strong pathway, but not in the weak pathway. (C) Tetanic stimulation of both the weak and the strong pathway together causes LTP in both the weak and the strong pathway. *Modified from Nicoll et al. (1988).*

small number of stimulated afferents, and the other termed the *strong* pathway with a large number of stimulated afferents (Fig. 47.8C). HFS of the *weak* input by itself failed to produce LTP in that pathway unless this stimulation was paired with tetanic stimulation of the *strong* input. Thus, LTP was induced in a *weak* input only when its activity was associated with activity in the *strong* input.

Input specificity means that LTP is restricted to only the inputs that received the tetanic stimulation. An unstimulated *weak* pathway was not facilitated after the tetanus to the *strong* pathway (Fig. 47.8B).

A Hebbian Mechanism Explains the Properties of Long-Term Potentiation at the CA3–CA1 Synapse in the Hippocampus

How can these classical properties of LTP in the CA1 region of the hippocampus be explained? In the late 1940s, the Canadian psychologist Donald Hebb (1949) formulated a postulate regarding the conditions that cause synapses to change. His thinking proved to be influential and guided later experiments that probed the mechanisms behind LTP. According to Hebb's postulate:

> When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased. (p. 62)

In short, coincident activity in two synaptically coupled neurons was proposed to cause increases in the synaptic strength between them. Numerous modern interpretations of Hebb's postulate exist, but most are captured by the mnemonic: "Cells that fire together, wire together."

Could the classical properties of LTP all be consequences of synapses that obey a Hebbian rule? Possibly so if a critical amount of postsynaptic depolarization were a necessary condition for inducing LTP in active synapses. In this case, cooperativity would result when enough input fibers were stimulated to produce the critical amount of postsynaptic depolarization. Associativity would emerge from the fact that the strong input caused sufficient depolarization of the postsynaptic membrane during the presynaptic activity in the weak input. Input specificity would occur because LTP was induced only in those inputs to a neuron that were active at the same time that the cell was sufficiently depolarized by the strong input to that neuron. In other words, these classical phenomena could all be manifestations of a single underlying Hebbian mechanism at the CA3–CA1 synapse.

Not all forms of LTP are Hebbian, however. Examples of non-Hebbian LTP can be found at the mossy fiber–CA3 synapse in the hippocampus and at the parallel fiber–Purkinje cell synapse in the cerebellum. These results indicate that the classical properties of cooperativity, associativity, and input specificity are not universal.

Mechanisms for Induction, Expression, and Maintenance of Long-Term Potentiation

LTP Induction

It is currently thought that there are multiple mechanisms or at least multiple second-messenger pathways that can lead to persistent synaptic enhancement. Multiple mechanisms may also contribute to expression and maintenance.

CALCIUM IONS AND LTP

It is generally agreed that the induction of LTP depends on an increase in the intracellular concentration of calcium ions ($[Ca^{2+}]_i$) in some key compartments of pre- and/or postsynaptic cells (Bliss & Collingridge, 1993; Johnston, Williams, Jaffe, & Gray, 1992; Nicoll & Malenka, 1995). The exact role of calcium in the induction process depends on the particular form of LTP and the synaptic system. In the CA1 region of the hippocampus, LTP induction in the Sch/com synapse depends on changes in postsynaptic

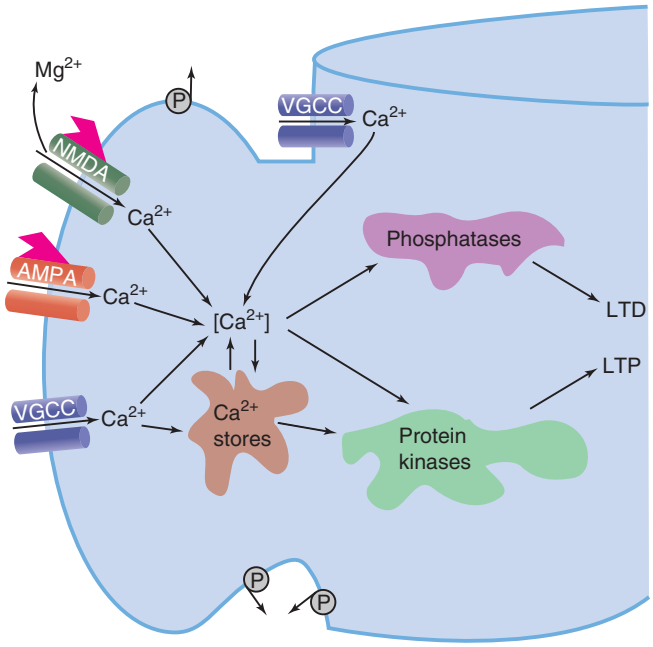

FIGURE 47.9 Events leading to some forms of LTP and LTD. The schematic depicts a postsynaptic spine with various sources of Ca^{2+}. The NMDA receptor channel complex admits Ca^{2+} only after depolarization removes the Mg^{2+} block in the presence of bound glutamate. Calcium may also enter through the ligand-gated AMPA receptor channel or voltage-gated calcium channels (VGCC), which may be located on the spine head or dendritic shaft. Calcium pumps (P), located on the spine head, neck, and dendritic shaft, are hypothesized to help isolate Ca^{2+} concentration changes in the spine head from those in the dendritic shaft.

$[Ca^{2+}]_i$ (Fig. 47.9). Two major pathways that have been studied extensively are implicated in some aspect of LTP induction: calcium influx through ionotropic GluRs, especially the *N*-methyl-D-aspartate receptor (NMDAR); and calcium influx through voltage-gated calcium channels (VGCCs).

NMDAR-DEPENDENT LTP

Recall that the classical form of LTP in the CA1 region of the hippocampus has properties that can be explained in terms of a Hebbian mechanism. For this form of LTP, considerable evidence shows a role for the NMDAR (Bliss & Collingridge, 1993). Numerous pharmacological studies have shown that competitive antagonists of NMDA, such as D-2-amino-5-phosphonopentenoic acid (D-AP5, also termed AP5 or APV) or NMDA ion channel blockers, such as the noncompetitive antagonist (+)-5-methyl-10, 11-dihydro-*5H*-dibenzo[*a,d*] cyclohepten-5,10-imine (MK-801), can prevent the induction of LTP.

The NMDAR has two properties that immediately suggest the nature of its role in LTP induction at Hebbian synapses (Bliss & Collingridge, 1993; Brown et al., 1990; Gustafsson & Wigstrom, 1988). First, NMDARs are permeable to Ca^{2+} (in addition to Na^+ and K^+). This property is significant because postsynaptic $[Ca^{2+}]_i$ plays a critical role in inducing NMDAR-dependent LTP. Second, the channel permeability is a function of both pre- and postsynaptic factors. Channel opening requires the neurotransmitter glutamate (or some related agonist) to bind to the NMDA site. This in turn requires presynaptic activity for glutamate release. At the usual resting membrane potential, the ionic channels of NMDARs are normally blocked by magnesium ions (Mg^{2+}), but this channel block is relieved by sufficient depolarization of the postsynaptic membrane. Thus, the NMDAR-mediated conductance is voltage dependent, allowing Ca^{2+} entry only when presynaptic release is combined with postsynaptic depolarization.

At this point, you should recall the distinction between the properties of the NMDAR and those of the AMPAR (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor) (see Chapters 8 and 10 for details), which are also found in the postsynaptic membrane. The AMPAR does not exhibit voltage-dependent Mg^{2+} block, has relatively lower Ca^{2+} permeability, and the AMPAR-mediated conductance is essentially voltage independent. Released glutamate can potentially act on both the AMPARs and the NMDARs associated with the membrane on the dendritic spine (Fig. 47.9). With this knowledge, one can easily envision a possible role for the AMPAR and NMDAR in a Hebbian modification. Nearly concurrent presynaptic activity (producing glutamate release and binding) and postsynaptic depolarization (relieving the Mg^{2+} block) allow Ca^{2+} influx into the dendritic spine of the postsynaptic neuron. The increased $[Ca^{2+}]_i$ in some critical region of the dendritic spine, presumably very close to the NMDAR, is thought to activate Ca^{2+}-dependent enzymes, such as CaM kinase II, which play a key role in LTP induction (Fig. 47.9).

In qualitative terms, one can understand how these molecular events could help account for the properties of cooperativity, associativity, and spatiotemporal specificity. Active synapses release glutamate, which can bind to the NMDAR, causing Ca^{2+} influx into dendritic spines on the postsynaptic cell. This Ca^{2+} influx acts locally and results in input-specific LTP. However, the Ca^{2+} influx occurs only when the synaptic input is strong enough to depolarize the postsynaptic membrane sufficiently to relieve the Mg^{2+} block, giving rise to cooperativity (Fig. 47.8). The depolarization itself is mediated in large part by the (voltage-independent) AMPARs, which are also colocalized on the dendritic spine (Fig. 47.9). Note that activity in a weak input by itself would not depolarize the postsynaptic cell sufficiently to relieve the Mg^{2+} block unless this activity were properly timed in relationship to activity in a strong input to the same cell. The combined depolarization of the two inputs gives rise to associativity and input specificity (Fig. 47.8).

NMDAR-INDEPENDENT LTP

Most of the preceding accounts of the Hebbian, NMDAR-dependent form of LTP apply only to certain synapses under some conditions, and even then it may be only one aspect of the story (Johnston et al., 1992; Nicoll & Malenka, 1995). In many synapses, LTP induction does not appear to require the NMDAR (Johnston et al., 1992; Teyler et al., 1994). Even within the hippocampus, some synapses exhibit NMDAR-independent forms of LTP. For example, in the presence of the competitive antagonist APV, even the Sch/com inputs to CA1 pyramidal neurons, which are known to exhibit the classical Hebbian form of LTP that relies on the NMDAR, can exhibit an NMDAR-independent type of LTP. The onset of NMDAR-independent LTP is relatively slow (20–30 min), exhibits input specificity, and is prevented by a blocker of L-type voltage-gated calcium channels (VGCCs). Thus, a distinction exists between "NMDA LTP" and "VGCC LTP." Other work has suggested that VGCCs are likely to be responsible for certain types of LTP in the CA3 region of the hippocampus and in the visual cortex.

The general case may be that both NMDAR-dependent and NMDAR-independent forms of LTP may coexist in the same brain region, among different classes of synaptic inputs onto the same postsynaptic neuron, and even among the same class of synaptic inputs to the same postsynaptic neuron.

INDUCTION OF LATE LTP

A common requirement for the induction of both early LTP and late LTP at the CA3–CA1 synapse is the elevation of levels of intracellular calcium in the postsynaptic (i.e., CA1) neuron. Additional steps are involved in the induction of L-LTP, however. As was the case for the induction of long-term facilitation of the sensorimotor synapse in *Aplysia*, activation of PKA appears to be necessary for the induction of L-LTP (Huang, Nguyen, Abel, & Kandel, 1996). However, in the CA1 neuron the cAMP pathway is engaged directly by the activation of a calcium-sensitive adenylyl cyclase rather than being activated by 5-HT as in *Aplysia*. (Transmitters that regulate cAMP in CA1 neurons can profoundly modulate LTP, however.) Thus, at the CA1 neuron elevated levels of calcium lead to activation of adenylyl cyclase, increased synthesis of cAMP, and activation of PKA. Also, like long-term facilitation in *Aplysia*, MAPK is necessary for the induction of L-LTP (Dineley et al., 2001). The mechanisms of activation of MAPK in CA1 neurons have not been elucidated in detail, but may involve PKA, PKC, or both acting together. The final steps in the induction of L-LTP involve a PKA- and MAPK-dependent phosphorylation of CREB and induction of CREB responsive genes. These genes encode the proteins underlying changes at the synapse (but see Box 47.1).

The mechanisms underlying the induction of long-term neuronal plasticity and memory seem to be highly conserved across species. NMDAR-dependent LTP has been characterized at the sensorimotor synapse of *Aplysia* (Lin & Glanzman, 1994). Formation of some long-term memories in *Drosophila* depends on both an increase in the activity of a transcriptional activator of the bZip family, dCREB2a, and a decrease in the activity of a related repressor, dCREB2b. Establishment of LTM in *Drosophila* therefore appears analogous to induction of *Aplysia* LTF, involving transcriptional activation by one bZip family member (CREB1 in *Aplysia*) and relief of

BOX 47.1

IS MEMORY MORE THAN CHANGES IN SYNAPTIC STRENGTH?

The search for the biological basis of learning and memory has led many of the leading neuroscientists of the twentieth century to direct their efforts to investigating the synapse. The focus of most recent work on LTP (and indeed the bulk of this chapter) has been to elucidate the mechanisms underlying changes in synaptic strength. Although changes in synaptic strength are certainly ubiquitous, they are not the exclusive means for the expression of neuronal plasticity associated with learning and memory. Both short-term and long-term sensitization and classical conditioning of defensive reflexes in *Aplysia* are associated with an enhancement of excitability of the sensory neurons in addition to changes in synaptic strength. Classical and operant conditioning of feeding behavior in *Aplysia* also leads to changes in excitability of neuron B51. Interestingly, in this case there is a bidirectional control. The excitability of B51 is increased by operant conditioning, whereas it is decreased by classical conditioning. Changes in excitability of sensory neurons in the mollusc *Hermissenda* are produced by classical conditioning. In vertebrates, classical conditioning of eye-blink reflexes produces changes in the excitability of cortical neurons. Eye-blink conditioning also produces changes in the spike afterpotential of hippocampal pyramidal neurons. Finally, as described in their original report on LTP, Bliss and Lomo found that the expression of LTP was also associated with an apparent enhanced excitability. For recent review see Mozzachoidi and Byrne (2010).

John H. Byrne

repression by another member (CREB2 in *Aplysia*). CREB activation also correlates with mammalian long-term memories. Interference with CREB function can inhibit long-term memories whereas overexpression of CREB can facilitate them.

LTP Expression

Up to this point, evidence related to early events in the causal chain that triggers the induction process has been emphasized. Another question follows naturally: What biochemical and biophysical changes incorporate this modification once it has been triggered? Most of the ideas about enhanced synaptic transmission concern either increased transmitter release or increased receptivity to released transmitter. The former entails presynaptic changes the latter, postsynaptic. Although some of the induction mechanisms discussed previously implicated a postsynaptic increase in $[Ca^{2+}]_i$, this does not necessarily imply that expression must also be postsynaptic. Ample evidence is available for ongoing two-way communication across the synaptic cleft, so a postsynaptic trigger could, in principle, give rise to a pre- and/or postsynaptic modification (see also Fig. 47.5). Extensive and seemingly conflicting accounts can be found in the literature regarding the nature of the changes responsible for the observed increase in synaptic efficacy following LTP induction. Some of the possibilities are illustrated schematically in Figure 47.10. However, regarding LTP at the CA3–CA1 synapse, the expression of LTP is associated with an increase in the number of functional AMPA receptors in the postsynaptic neuron (*mechanism No. 5* in Fig. 47.10; for review, see Malinow & Malenka, 2002). LTP at this synapse also involves phosphorylation of the AMPA receptor, which leads to an increased conductance that contributes to enhanced synaptic efficacy (*mechanism No. 4* in Fig. 47.10). Recent results indicate that a family of small transmembrane AMPA receptor regulatory proteins (TARPs) controls both AMPA receptor trafficking and channel gating. Finally, LTP at hippocampal and cortical excitatory synapses correlates with increases in the size of dendritic spines on the postsynaptic neurons (reviewed in Kasai, Fukuda, Watanabe, Hayashi-Takagi, & Noguchi, 2010).

In contrast to the predominant evidence for postsynaptic expression of LTP at the CA3–CA1 synapse (see, however, Enoki, Hu, Hamilton, & Fine, 2009), LTP at the mossy fiber–CA3 synapse appears to involve an increase in transmitter release.

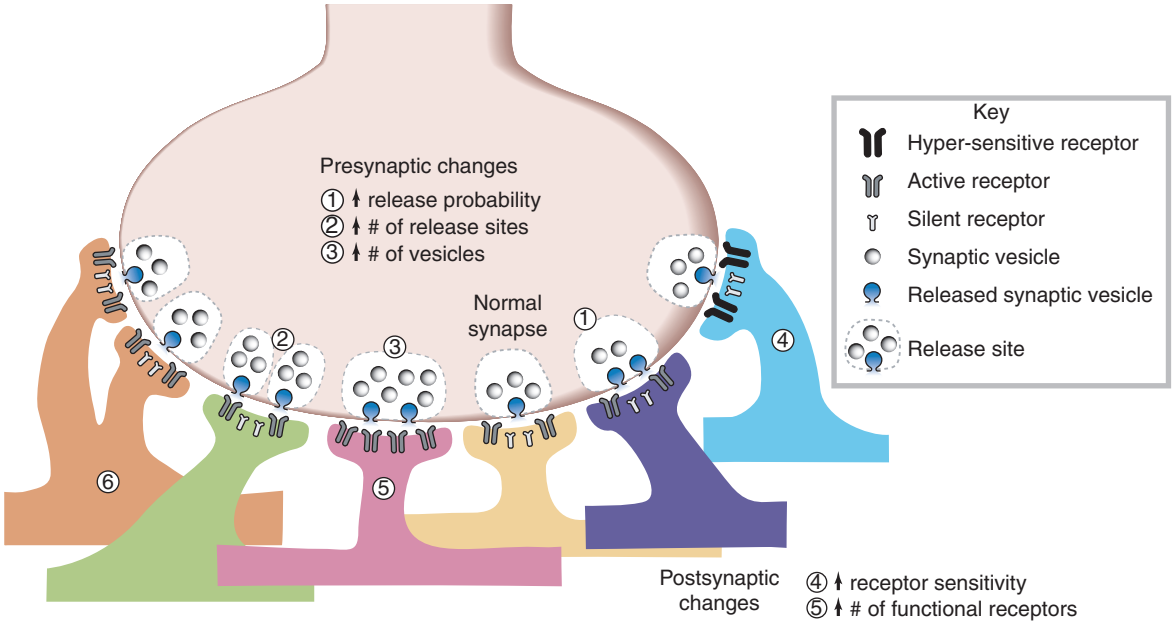

FIGURE 47.10 Schematic representation of possible loci for cellular changes involved in the enhancement of synaptic efficacy. The efficacy of a synapse can be potentiated through at least six mechanisms. First, there could be an increase in the fraction (release probability) of available presynaptic vesicles that undergo exocytosis. For example, in *mechanism 1*, two out of four available vesicles are released (i.e., 50% release probability), in contrast to the *normal synapse*, where only one out of four vesicles is released (i.e., 25% release probability). Second, there could be an increase in the number of release sites at the presynaptic neuron (*mechanism 2*). Third, the synapse could be potentiated through an increase in the number of vesicles available for release. For example, at a release site with eight vesicles, two of them will be exocytosed (instead of one) (*mechanism 3*), even if the release probability (25%) is the same as at the normal synapse. Fourth, there could be an increase in the sensitivity of the preexisting receptors to presynaptically released neurotransmitter or a greater conductance of the channel (*mechanism 4*). Fifth, there could be an increase in the number of functional receptors (illustrated as an increase from two active receptors at the normal synapse to four at the potentiated synapse; *mechanism 5*). Finally, the synapse could also be potentiated through coordinated presynaptic and postsynaptic morphological changes, such as the growth of new synaptic contacts between the same pair of neurons (*mechanism 6*). *Adapted from Wang, Ko, and Kelly (1997).*

LTP Maintenance

Regardless of the ultimate nature and locus of the modification that gives rise to LTP expression, the more general problem remains of how a synaptic change can endure over long periods of time in the face of constant molecular turnover.

MAINTENANCE OF EARLY LTP

The maintenance of E-LTP is due to the persistence of phosphorylation of substrate proteins involved in expression mechanisms (see earlier discussion). This phosphorylation, in turn, is regulated by the engagement of protein kinases and phosphatases. For E-LTP, autonomously active forms of PKC and CaM kinase II appear to be particularly important.

MAINTENANCE OF LATE LTP

The maintenance of persistent forms of LTP ultimately involves alterations in gene expression and changes in protein synthesis. High-frequency electrical stimulation in the rat hippocampus raises levels of specific mRNAs that encode transcription factors (e.g., Fos, zif268), cytoskeletal proteins (e.g., Arc), and signal transduction molecules such as CaM kinase II. Moreover, protein synthesis inhibitors block the late phase of LTP but not earlier phases. One interesting observation is that brain slices that received protein synthesis inhibitors just 2 h after HFS showed no decline in late LTP, indicating that there is a critical time window during which protein synthesis might be necessary to maintain long-term plasticity. One protein PKMζ appears both necessary and sufficient for maintenance of a least some forms of L-LTP and seems necessary for maintaining the increase in postsynaptic AMPA receptors (Sacktor, 2011).

Although the involvement of new protein synthesis is consistent with the data, it immediately raises the problem of synaptic input specificity. If neural activity ultimately affects gene expression in the nucleus, then the mRNAs and proteins produced in the somatic compartment could, in principle, travel to any synapse within the cell. The problem is how to modify only the appropriate synapses and maintain synapse specificity. One solution is for the specific kinase(s) activated locally during a tetanus to phosphorylate one or more substrates and that these substrates act to "tag" the synapse as one that has been potentiated. For example, a stimulus that activates one CA1 synaptic input sufficiently to induce L-LTP can lead to the induction of L-LTP by a weaker stimulus to a second synaptic input even when that second input is by itself sufficient to only induce E-LTP. This effect is limited to a time window where the second weaker stimulus occurs within an hour or so of the stronger one. These results indicate that the weaker stimulus can lead to the transient (~1 h) activation of a synaptic "tag" that can specificially "capture" "plasticity factors" induced by a strong stimulus to a different synapse (Redondo & Morris, 2011). A major goal of current LTP research is to identify the nature of the tag and the plasticity factors.

Support of a more permanent synaptic modification might require a self-perpetuating tag and/or a biochemical positive feedback loop that maintains synaptic strength (Hayer & Bhalla, 2005). One possibility is that CPEB, the prion-like molecule that has been implicated in *Aplysia* LTF (Miniaci et al., 2008), might help to maintain synthesis of PKMζ (Sacktor, 2011). Positive feedback based on network activity may also be important. Periodic reactivation of strengthened synapses may be necessary to reactivate mechanisms of L-LTP, maintaining synaptic strength for months or longer (Smolen, 2007; Wang & Tsien, 2006).

Links between Long-Term Potentiation and Learning

Long-term potentiation has properties that have long been considered necessary for the encoding and retrieval of information. Hebbian forms of LTP exhibit associativity, which appears to be a desirable property, and all forms of LTP appear to be well suited to rapid learning. One of the more important challenges entails linking LTP (and LTD, see later) to learning and memory. This task has proven rather difficult to achieve, although evidence is accumulating for a causal link between LTP and memory. For example, learning in rats was verified to induce hippocampal LTP (Whitlock, Heynen, Shuler, & Bear, 2006). Also, inhibition of PKMζ in the hippocampus *in vivo* was demonstrated to disrupt LTP maintenance and eliminate spatial learning. Instrumental and classically conditioned long-term memories are similarly erased by locally inhibiting PKMζ in different brain regions of rats and mice, from days to even weeks and months after training (Saktor, 2011; Serrano et al., 2008). These results have greatly strengthened the link between LTP and learning. However, inhibiting PKMζ does not erase all forms of memory (Serrano et al., 2008).

Additional promising work in this area has come from studies of genetically engineered knockout mice. The first generation of knockouts prevented the expression of some factor that was thought to be necessary for LTP, such as CaM kinase II. Although these studies were intriguing, they suffered from the fact that the consequences of a gene knockout might alter brain development and might not be confined to a specific part of the brain under study. Some of these problems have been overcome in a second generation of knockouts that have temporal as well as spatial specificity. For example, temporal and spatial control of gene expression can now be achieved using binary transgene systems such as tetracycline transactivating systems and Cre/LoxP recombination systems. The NMDAR gene in only CA1 pyramidal cells of the hippocampus has been

knocked out using the Cre/LoxP system (Tsien, Huerta, & Tonegawa, 1996). The results provide strong evidence in favor of the notion that NMDA receptor-dependent synaptic plasticity at CA3–CA1 synapses is required for the acquisition of spatial memory. Further spatial specificity can be obtained by using promoters that are specific for subfields of the hippocampus. For example, one of the kainate receptor subunits, KA-1, exhibits high levels of expression in the CA3 pyramidal cell layer. Using the KA-1 promoter and the α-CaM kinase II promoter, Nakashiba, Young, McHugh, Buhl, and Tonegawa (2008) drove expression of tetanus toxin specifically in CA3 neurons. Expression of the toxin inhibited transmitter release from CA3 neurons which was associated with a block of one-trial contextual learning. Similar approaches using cell-specific promoters to drive expression of toxins or their receptors have been used to examine the role of cerebellar circuits that mediate classical conditioning of eye-blink reflexes (for review, see Nakanishi, 2009). The molecular approaches described above hold tremendous promise for testing hypotheses of the functional role of various forms of LTP in specific brain regions as well as the role of specific neural circuits in mediating memory processes.

LONG-TERM DEPRESSION

LTD is believed by many to be the mechanism by which learning is encoded in the cerebellum (Ito, 2001), as well as a process whereby LTP could be reversed in the hippocampus and neocortex (Bear & Malenka, 1994). In the hippocampus, brief HFS (e.g., four trains of 10 shocks at 100 Hz) can induce classical LTP, whereas low-frequency stimulation (LFS) over longer periods (1 Hz for 10 min) can induce LTD.

Some forms of LTD appear to be mediated by the NMDAR and these forms appear to be due to dephosphorylation of AMPAR subunits, which decreases their conductance and hence the synaptic efficacy, as well as endocytosis of AMPARs, which decreases their surface number and hence the synaptic efficacy. In addition, NMDAR-independent forms of LTD exist. These often depend on activation of metabotropic glutamate receptors. For example, NMDAR-independent LTD in the parallel fiber input to Purkinje cells in the cerebellum is induced by the combined increase in intracellular levels of Ca^{2+} (by activity) in postsynaptic Purkinje cells and activation of metabotropic glutamate receptors produced by the release of glutamate from parallel fibers.

The form of LTD may vary in different brain regions and sometimes among different inputs to the same brain region. Even within the CA1 region, the Sch/com input may exhibit both NMDAR-dependent and NMDAR-independent forms of LTD.

Calcium levels in the dendritic spines appear to be a common locus for the induction of NMDAR-dependent LTP and LTD. For example, at the Sch/com input to CA1, both LTP and LTD can be blocked by injecting Ca^{2+} chelators into the postsynaptic cell. If both LTP and LTD are triggered by Ca^{2+} entry, then how are their induction processes different? Presumably, more Ca^{2+} influx occurs during an LTP-inducing HFS than during an LTD-inducing LFS. One formal molecular model developed by John Lisman incorporates this Ca^{2+}-dependent, bidirectional control of synaptic strength. In this model, high $[Ca^{2+}]_i$ activates a protein kinase that phosphorylates a protein causing LTP induction, whereas intermediate $[Ca^{2+}]_i$ activates a protein phosphatase that dephosphorylates this protein and causes LTD. The synaptic strength thus depends on which of these competing processes is most active, which in turn will be a function of the pattern of activity experienced by the cell (Fig. 47.9).

LTP and LTD can be readily reversed. If LFS is applied after a synapse is potentiated by HFS, the synaptic strength decreases. This phenomenon is called depotentiation. In contrast, if HFS is applied after a synapse is depressed by LFS, the synaptic strength increases. This phenomenon is called dedepression. Accumulating evidence indicates that the mechanisms of depotentiation differ from that of LTD, and the mechanisms of dedepression differ from that of LTP.

Summary

The understanding of LTP and LTD is evolving rapidly (Bliss, Collingridge, & Morris, 2007). For example, whereas the *N*-methyl-D-aspartate receptor was once the pivotal focus of long-term potentiation research, it is now clear that other mechanisms should be considered. It has also become evident that HFS is but one end of a spectrum of stimulations that can induce synaptic changes. Lower stimulation frequencies can induce long-term depression, which may share some common molecular mechanisms with LTP. Finally, several stages in the maintenance of LTP have been identified, and probably more will be found. A remaining challenge is to clarify the varieties of LTP and LTD mechanisms and to demonstrate their functional significance by establishing convincing links to the encoding and retrieval of information.

HOW DOES A CHANGE IN SYNAPTIC STRENGTH STORE A COMPLEX MEMORY?

The relationship between the synaptic changes and the behavior of conditioned reflexes can be straightforward because the locus for the plastic change is part of the mediating circuit. Thus, the change in the strength of the

sensorimotor synapse in *Aplysia* can be related to the memory for sensitization (e.g., Fig. 47.2A1). However, the idea that an increase in synaptic strength leads to an enhanced behavioral response, and a decrease in synaptic strength leads to a decreased behavioral response, can be misleading. For example, a decrease in synaptic strength in a postsynaptic neuron that exerts an inhibitory action can be translated into an enhanced behavioral response. Indeed, in the parallel fiber-to-Purkinje cell connection in the cerebellum, such a disinhibition is precisely the mechanism that has been proposed to contribute to classical conditioning of the eye-blink reflex (see Chapter 48 for a discussion of this form of conditioning). Nevertheless, for relatively simple reflex systems in which the circuit is well understood, it is possible to directly relate a change in synaptic strength to learning. However, in most other examples of memory, it is considerably less clear how the synaptic changes are induced and, once induced, how the information is retrieved. This is especially true in memory systems that involve the storage of information for patterns, facts, and events. Neurobiologists have turned to artificial neural circuits to gain insights into these issues.

A simple network that can store and "recognize" patterns is illustrated in Figure 47.11. The network is artificial, but nevertheless is inspired by actual circuitry in the CA3 region of the hippocampus. In this example, six different input projections make synaptic connections with the dendrites of each of six postsynaptic neurons (Fig. 47.11A). The postsynaptic neurons serve as the output of the network. Input projections can carry multiple types of patterned information, and these patterns can be complex. In order to simplify the present discussion, consider that the particular input pathway in Figure 47.11A carries information regarding the pattern of neural activity induced by a single brief flash of a spatial pattern of light. For example, activity in the top pathway (line *a*) might represent light falling on the temporal region of the retina, whereas activity in the pathway on the bottom (line *f*) might represent light falling on the nasal region of the retina. Thus, the spatial pattern of an image falling upon the retina could be reconstructed from the pattern of neuronal activity over the *n* (in this case 6) input projections to the network.

Three aspects of the circuit endow it with the ability to store and retrieve patterns. First, each of the input lines makes a sufficiently strong connection with its corresponding postsynaptic cell to activate it reliably. Second, each output cell (*z* to *u*) sends an axon collateral that makes an excitatory connection with itself as well as the other five output cells. This pattern of synaptic connectivity leads to a network of 36 synapses (42 including the 6 input synapses). Third, each of the 36 synaptic connections is modifiable through an LTP-like mechanism (see earlier discussion). Specifically, the strength of a particular synaptic connection is initially weak, but it will increase if the presynaptic *and* postsynaptic neurons are active at the same time. The circuit configuration with the embedded synaptic "learning rule" leads to an autoassociation or autocorrelation matrix. The autoassociation is derived from the fact that the output is fed back to the input where it associates with itself.

Now consider the consequences of presenting the patterned input to the network of Figure 47.11A. The input pattern will activate the six postsynaptic cells in such a way as to produce an output pattern that will be a replica of the input pattern. In addition, the pattern will induce changes in the synaptic strength of the active synapses in the network. For example, synapse 3 will be strengthened because the postsynaptic cell, cell *z*, and the presynaptic cell, cell *x*, will be active at the same time. Note also that synapses 1, 5, and 6 will be strengthened as well. This occurs because these input pathways to cell *z* are also active. Thus, all synapses that are active at the same time as cell *z* will be strengthened. When the pattern is presented again as in Figure 47.11B, the output of the cell will not only be governed by the input, but also by the feedback connections, a subset of which were strengthened (Fig. 47.11B, filled synapses) by the initial presentation of the stimulus. Thus, for output cell *z*, a component of its activity will be derived from input *a*, but components will also come from synapses 1, 3, 5, and 6. If each of the initially strong and newly modified synapses is assumed to contribute equally to the firing of output cell *z*, the activity would be five times greater than the activity produced by input *a* before the learning. After learning, the output is an amplified version of the input but the basic features of the pattern are preserved.

Note that the "memory" for the pattern does not reside in any one synapse or in any one cell. Rather, it is *distributed* throughout the network at multiple sites. The properties of these types of autoassociation networks have been examined by James Anderson, Teuvo Kohonen, David Marr, Edmond Rolls, David Wilshaw, and their colleagues and found to exhibit a number of phenomena that would be desirable for a biological recognition memory system. For example, such networks exhibit pattern completion. If a partial input pattern is presented, the autoassociation network can complete the pattern in the sense that it can produce an output that is approximately what is expected for the full input pattern. Thus, any part of the stored pattern can be used as a cue to retrieve the complete pattern. For the example of Figure 47.11, the input pattern was {101011}. This pattern led to an output pattern of {505055}. If the input pattern is degraded to {101000}, then neurons *z* and *x* each receive two less recurrent inputs, and neurons *v* and *u* each receive two less recurrent inputs and lose their direct input. Nevertheless neurons *z*, *x*, *v*, and *u* each still receive two recurrent inputs and neurons *z* and *x* receive direct inputs. Therefore, these four neurons fire,

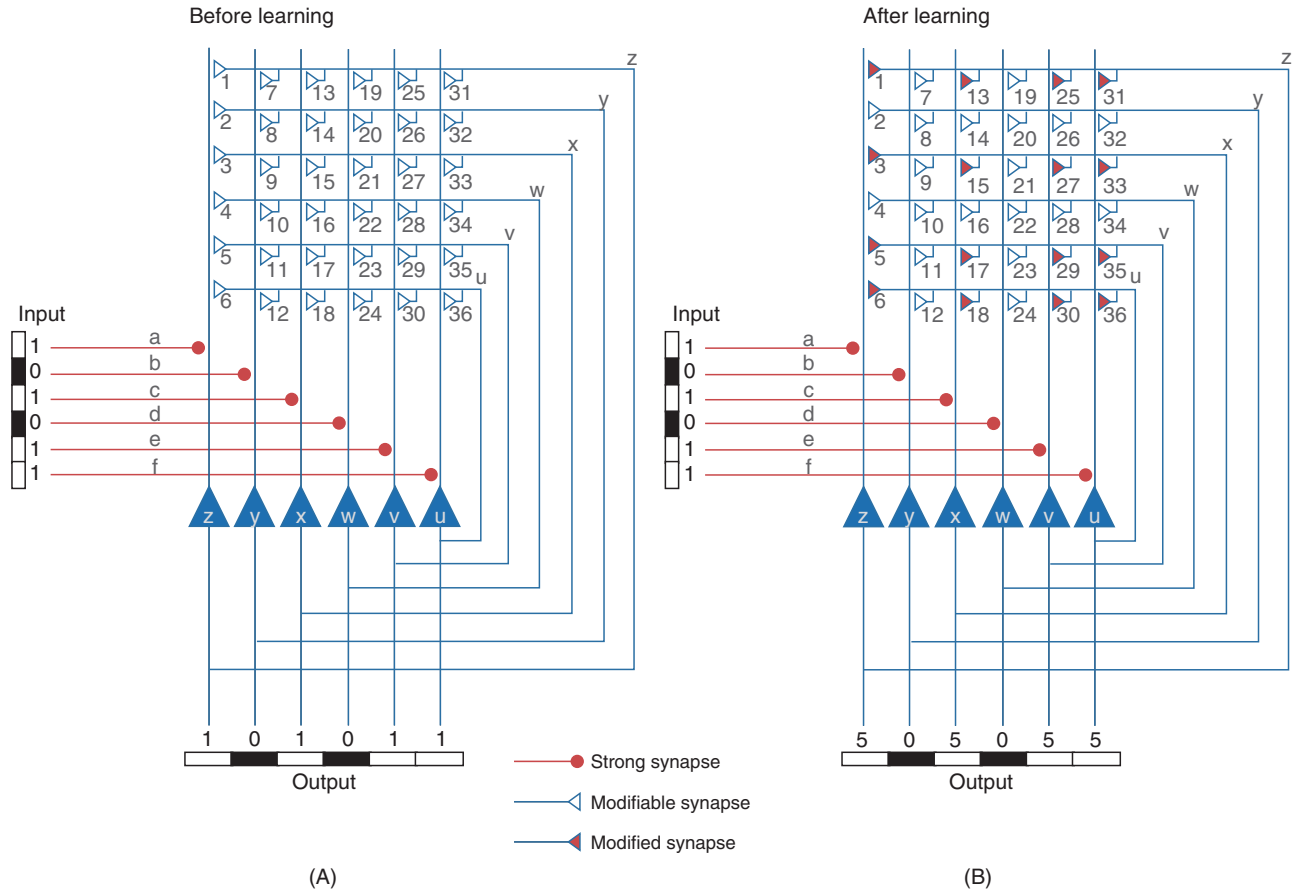

FIGURE 47.11 Autoassociation network for recognition memory. The artificial circuit consists of six input pathways that make strong connections to each of six output neurons. The output neurons have axon collaterals that make synaptic connections (numbered 1–36) with each of the output cells. (A) A pattern represented by activity in the input lines or axons (a, b, c, d, e, f) is presented to the network. A 1 represents an active axon (e.g., a spike), whereas a 0 represents an inactive axon. The input pathways make strong synapses (•) with the postsynaptic output cells. Thus, output cells (u, v, w, x, y, z) generate a pattern that is a replica of the input pattern. The collateral synapses were initially weak and do not contribute to the output. Nevertheless, the activity in the collaterals that occurred in conjunction (assume minimal delays within the circuit) with the input pattern led to a strengthening of a subset of the 36 synapses. (B) A second presentation of the input produces an output pattern that is an amplified, but an otherwise intact, replica of the input. An incomplete input pattern can be used as a cue to retrieve the complete pattern.

and the output pattern is {303022}. Compared to the original output pattern {505055}, some decrease in the strength of firing occurs, but the basic pattern is preserved. This preservation is a simple example of the phenomenon known as graceful degradation, which is exhibited by autoassociative networks. With graceful degradation, the network can still function if some of the input connections or postsynaptic cells are lost. This property arises from the distributed representation of the memory within the circuit.

Summary

The concept of distributed representation of memory crosses multiple levels of organization of memory systems. Multiple brain systems are involved in memory, and memory is distributed among synapses in a particular memory circuit (Fig. 47.11). Also, memory at any one synapse is represented by multiple cellular changes (Figs. 47.2, 47.3, and 47.9). The reductionist approaches described in this chapter have provided key insights into cellular memory mechanisms. In the near future, a major experimental question to be answered is the extent to which the mechanisms for learning are common both within any one animal and between different species. Although many common features are emerging, there seem to be some differences. Thus, it will be important to understand the extent to which specific mechanisms are used selectively for one type of learning and not another. Irrespective of the particular example of learning and memory that is analyzed, whether it be simple or complex, it will be important to pay attention to three major details: details of the circuit interactions, details of the learning rule, and details of the intrinsic biophysical properties of the neurons within the circuit.

CHAPTER

48

Learning and Memory: Brain Systems

INTRODUCTION

The topic of memory systems can be usefully framed by the question of whether a specific memory can be localized or whether it is distributed throughout the brain. Even early on there was evidence that the answer might lie somewhere between these extremes. In the 1920s, the psychologist Karl Lashley conducted a series of experiments in which he carefully damaged various areas in the cerebral cortex of rats that had learned a route through a simple maze. He found that the total amount of cortex damaged correlated with the severity of memory impairment, irrespective of the specific location of the brain damage. Lashley therefore concluded that memory was distributed throughout the brain. Yet a short time later, the neurosurgeon Wilder Penfield found that when he stimulated various areas of the brains of awake epileptic patients (in order to identify functional areas deemed too important to be removed during surgery to treat the epilepsy), stimulation in some brain regions led the patient to experience specific memories. He reasoned that, if focal stimulations bring specific memories to mind, then memories might be localized in specific brain regions. The psychologist Donald Hebb offered reconciliation by suggesting that thoughts and memories were supported by "cell assemblies," or networks of neurons, and that experience resulted in changes in the connections between cells (Hebb, 1949). Thus, to the extent that a change at an individual juncture between cells (i.e., a synapse) recorded experience, memory was localized. Yet to the extent that full memories resulted from a reactivation of entire cell assemblies, memory was distributed.

The previous chapter discussed how synapses can be strengthened and weakened, and the current chapter considers how this synaptic plasticity supports behavior through memory systems, distributed cell assemblies involving a large number of interconnected neurons. A memory system is most usefully defined in both psychological and anatomical terms. That is, a memory system is most clearly identified by both a distinct neural circuitry and a unique set of operating characteristics. Memory systems are not separated according to stimulus modality (e.g., auditory vs. visual modality) or response modalities (e.g., manual vs. verbal responses). Instead, the critical distinctions involve how the biology of each system's anatomy and physiology support a particular type of memory representation in computational, psychological, and behavioral terms.

The present chapter focuses on individual structures that play central roles in each of the different systems and includes separate sections on the hippocampus, striatum, cerebellum, amygdala, and cerebral cortex (Fig. 48.1). Each of these structures anchors a much larger network of distributed brain areas that work in concert to support particular forms of memory. For example, the hippocampal memory system involves not only the hippocampus but also areas in the adjacent parahippocampal region and is connected to many distributed unimodal and polymodal neocortical areas. These areas normally work together to support conscious recollection of facts and events, a capacity termed declarative memory. Even though declarative memory depends on very specialized information processing and plasticity within the hippocampus, a complicated and distributed circuitry outside the hippocampus is also required for these alterations to emerge as the experience of remembering. Importantly, the cerebral cortex plays a role in many types of memory, and the present chapter will discuss

© 2013 Elsevier Inc. All rights reserved.

both its role as a part of multiple memory systems and the specific memory functions it supports outside of those systems. Finally, memory systems work in concert to support behavior in the course of one's day to day activities, and this issue will be considered in the final section of the chapter.

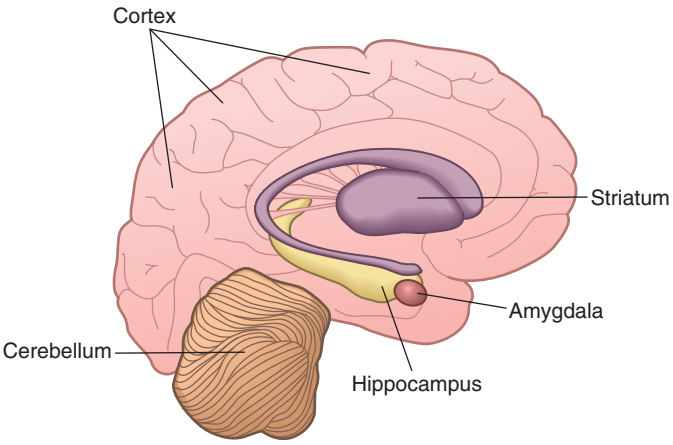

FIGURE 48.1 Drawing of the human brain showing components of the major memory systems.

Hippocampus

Anatomy

The hippocampal memory system includes the hippocampus (defined here as the CA fields, dentate gyrus, and subiculum) and the entorhinal, perirhinal, and postrhinal cortices in the adjacent parahippocampal region (the postrhinal cortex is referred to as the parahippocampal cortex in primates; Fig. 48.2; Burwell, Witter, & Amaral, 1995; Suzuki, 1996). The anatomy and circuitry of these regions, especially the hippocampus, are largely conserved across mammalian species (Manns & Eichenbaum, 2007). The parahippocampal region serves as a convergence site for input from cortical association areas and mediates the distribution of cortical afferents to the hippocampus. These parahippocampal cortical areas are interconnected and send major efferents to multiple subdivisions of the hippocampus. Within the hippocampus, an intricate pattern of connectivity mediates a large network of associations (Fig. 48.2; Amaral & Witter, 2004), and these connections support forms of long term potentiation that could participate in the rapid coding of novel conjunctions of information (see Chapter 47). The outcomes of hippocampal processing are directed back to the adjacent cortical areas in the parahippocampal region, and the outputs of that

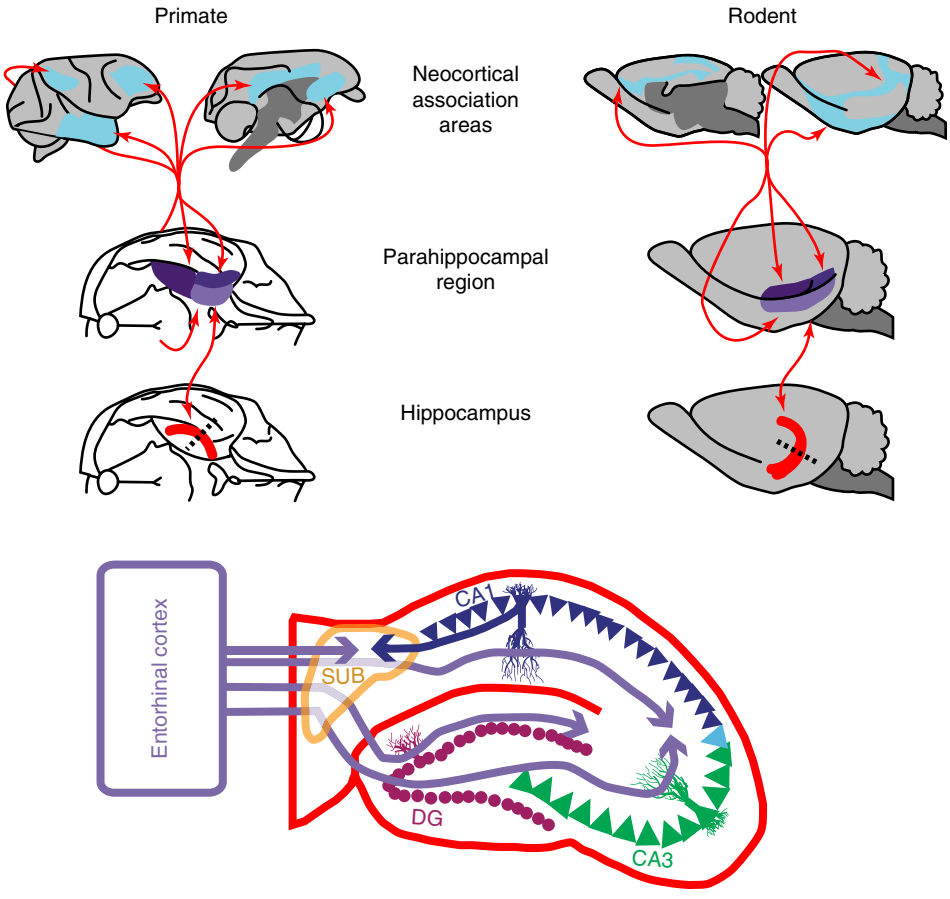

FIGURE 48.2 The anatomy of the hippocampal memory system in monkeys and rats. The hippocampal memory system includes the hippocampus (CA fields, dentate gyrus, and subiculum) and the parahippocampal region, which includes the entorhinal cortex, the perirhinal cortex, and the parahippocampal cortex. The hippocampal memory system also includes midline diencephalic nuclei. Multiple association areas in the cerebral cortex send outputs that converge on cortical areas in the parahippocampal region, which in turn sends its outputs to the hippocampus. The output path involves return projections from the hippocampus to the surrounding parahippocampal region, which in turn projects back to the same cortical association areas. The bottom image shows detailed entorhinal projections on a transverse section of the hippocampus (location of section indicated by dashed lines on the top image). *Top image from Eichenbaum (2001).*

region are directed in turn back to the same areas of the cerebral cortex that were the source of its inputs. Additional structures have also been included as components of this system, including midline diencephalic structures that are connected to the hippocampus via the fornix.

Patient H.M. and Amnesia

The study of the hippocampal memory system, and memory systems in general, began in earnest with a published case report about a man who underwent brain surgery to treat severe epilepsy and who became arguably the most famous patient in neuroscience (Scoville & Milner, 1957; Squire, 2009). This man, known as H.M., began experiencing seizures at the age of 10, and by his late twenties, he had developed a severe seizure disorder that interfered with his ability to live a normal life. Heavy doses of anticonvulsant medications did not stop the seizures from worsening, and the disorder eventually became debilitating. Acting on the idea that dysfunctional brain tissue in the temporal lobes might be causing the seizures, on September 1, 1953, the neurosurgeon William Scoville removed substantial tissue from the medial aspect of H.M.'s temporal lobes bilaterally, including the hippocampus and the parahippocampal cortical region (Fig. 48.3). In one sense, the surgery was a success. The frequency and severity of the seizures were reduced. In another sense, the outcome was tragic. On April 26, 1955, Brenda Milner, a colleague of both Penfield and Hebb, conducted a neuropsychological examination of patient H.M. His profound memory impairment was immediately obvious. H.M. gave the date as March 1953 and his age as 27 (two years younger than his actual age). He performed poorly on memory tests that involved short stories, word lists, pictures, and a wide range of other materials. Remarkably, it was unclear that he even remembered that he had undergone brain surgery. The severity of H.M.'s memory impairment was shocking: he showed almost no capacity for new learning. Yet the reason that H.M.'s case ushered in the modern era of research on memory stemmed from the appreciation that severe memory impairment could occur while other cognitive functions were intact.

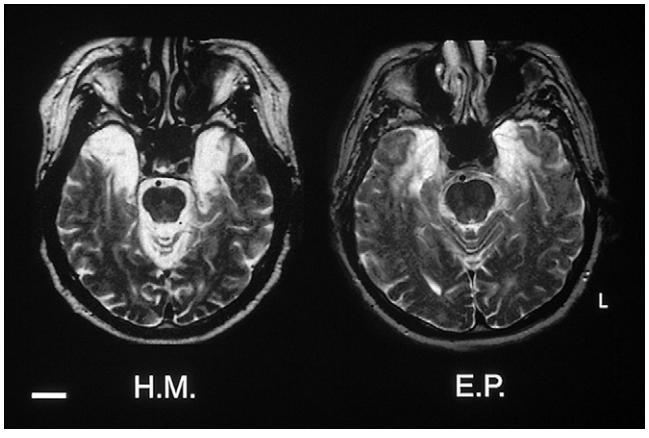

FIGURE 48.3 Magnetic resonance images showing the brains of amnesic patients H.M. and E.P. The images show axial sections through the medial temporal lobes and reveal damaged tissue as a bright signal. H.M.'s damage resulted from surgery, and E.P.'s damage was caused by viral encephalitis. Nevertheless, the resulting lesion was similar for the two patients. Both patients sustained extensive damage to the medial temporal lobes and are profoundly amnesic (from Stefanacci, Buffalo, Schmolck, & Squire, 2000).

First, formal testing identified that H.M.'s IQ score was generally unaffected by the surgery, and a battery of tests found no deficits in perception, abstract thinking, or reasoning ability. These intact abilities indicated that memory could be separated from perception and intelligence. Second, H.M. could hold on to small amounts of information as long as he was actively rehearsing the information. This finding suggested that the ability to maintain information online (now usually referred to as working memory) was distinct from the ability to make a lasting record in the brain (see Chapter 50). Third, H.M.'s childhood memories were relatively intact. This finding suggested that, although the medial temporal lobes might be important for forming new memories, this region was unlikely to be the final storage site for memory. Fourth, H.M. had an intact ability to acquire new motor and perceptual skills (Milner, 1962). As an example, over several days of practice, H.M. gradually improved at tracing the outline of a star when viewing the paper only through a mirror (a task that is initially challenging even for healthy individuals) despite never forming a conscious memory for the testing experience. These results indicated that memories outside the scope of conscious recollection depended on structures outside the medial temporal lobe.

Patient H.M.'s memory impairment is referred to as amnesia, and it includes both an anterograde component—the impaired ability to acquire new information—and a temporally-graded retrograde component—the loss of information acquired soon before the onset of brain damage. Amnesic patients, including H.M., have contributed fundamentally to our current understanding of the hippocampal memory system (see Box 48.1 for a discussion of memory impairments in Alzheimer's Disease). For example, one patient (R.B.) with damage largely restricted to one subfield of the hippocampus (CA1) showed that the hippocampus itself made essential contributions to memory (Zola-Morgan, Squire, & Amaral, 1986), although his memory impairment was more modest than H.M.'s. Perhaps most fundamental has been the repeated demonstration by numerous amnesic patients that the hippocampal memory system supports conscious recollection of facts and events (declarative memory), and that this type of memory is distinct from the type of memory supported by other brain systems, collectively referred to as nondeclarative memory. In most amnesic patients, the deficit in declarative memory encompasses all stimulus modalities and impacts nonverbal expression as well

BOX 48.1

ALZHEIMER'S DISEASE

Alzheimer's Disease (AD) is the most common disorder of memory in humans, afflicting approximately one in eight adults over age 65 (Alzheimer's Association, 2012). The only FDA-approved therapeutics for AD to date are acetylcholinesterase inhibitors and memantine, an NMDA-receptor antagonist, that provide palliative treatment. Since there is no disease-modifying treatment that slows or halts the progression of AD this represents one of the greatest healthcare crises to date. Two characteristic pathological hallmarks of AD are extracellular plaques of aggregated amyloid beta (Aβ) and intracellular neurofibrillary tangles (NFTs) composed of aggregated tau, a microtubule binding protein. Aβ is produced through the enzymatic cleavage (via secretases) of amyloid precursor protein (APP) and in some forms is toxic to neurons. Aβ can disrupt synaptic plasticity, including long-term potentiation. NFTs may compromise intracellular transport and—together with Aβ—kill neurons. Genetic studies from familial cases of AD have strongly pointed towards a causal role for amyloid in aggressive, early-onset forms of AD, with APP or secretase mutations sufficient to cause early-onset AD. However, it is important to realize that familial AD accounts for <1% of all AD cases, while >99% of AD cases are sporadic in nature. Finally, there are a variety of other pathophysiological processes also involved in AD including perturbations in energy metabolism, membrane traffic and signaling, oxidative stress, and inflammation. The precise sequence of events and their relative importance remain to be determined.

Neurodegeneration in AD progresses sequentially through certain brain structures and select subpopulations of vulnerable neurons (Holtzman, Morris, & Goate, 2011). AD almost invariably begins with an insidious, gradual decline in memory, specifically, with problems encoding new memories. Consistently impacted early are those neurons in layer II of the entorhinal cortex, which acts as a gatekeeper of information flowing to and from the hippocampus. Aβ and tau pathologies accumulate in a circuit-dependent manner, deafferenting the entorhinal cortical projections to the hippocampus, and disrupting the molecular mechanisms necessary to form new episodic memories. This results in patients becoming more forgetful and repeating conversations, losing their belongings, and often getting lost driving or otherwise spatially navigating. These initial disease symptoms reflect the increasing dysfunction of the medial temporal lobe memory system. Neuropsychological tests may be used to confirm memory loss and quantify problems of new learning, recall, and recognition memory for verbal and visual material. Additionally, functional MRI studies have demonstrated altered patterns of memory-related activation in the medial temporal lobe of individuals with prodromal AD. While the coding of nascent episodic memories is compromised in early AD, older semantic memories that have previously been consolidated in neocortex are relatively preserved.

As Aβ and tau pathologies become increasingly widespread with disease progression and lead to synaptic failure and neurodegeneration, early episodic memory impairment gives way to progressive deficits in other higher brain functions (Holtzman, Morris, & Goate, 2011). The number of affected neuronal circuits increases dramatically to impact frontal, cingulate, and parietal cortices such that executive function, language, perception, praxis, and visuospatial abilities become impaired. With advanced disease, damage to higher cortices can also disrupt skilled motor actions (praxis) and compromise long-term semantic memory. Beyond widespread cortical pathology, cholinergic basal forebrain (CBF) neurons along with neurons of the locus coeruleus (LC) and raphe nuclei are vulnerable. CBF degeneration contributes to AD symptoms including attention deficits, increased spatial memory decline and further impairment in the coding of new episodic memories. Loss of serotonergic raphe projections likely contributes to behavioral symptoms such as irritability, apathy, depression, mood lability, and aggression. Degeneration of LC neurons translates to noradrenergic transmission loss, which disrupts arousal, vigilance, sleep-wakefulness, working memory, and properly interpreting and responding to autonomic stressors. Additionally, LC degeneration can also perturb microglial function, yielding neurotoxic inflammation.

The pathophysiology of AD allows for several putative therapeutic avenues. At present, our systems-level understanding of AD has yielded pro-cholinergic treatment strategies including acetylcholinesterase inhibitors and NMDA antagonists for transmitter-based symptomatic treatments. Drug candidates are being advanced in clinical trials so that we might obtain the desperately needed therapeutics to slow or halt AD progression. A cellular and molecular understanding of AD has led to amyloid-based approaches including secretase inhibitors, disrupting Aβ aggregation and promoting amyloid clearance. Also under investigation are neurotrophin-based therapies to prevent the neurodegeneration of vulnerable neurons, anti-inflammatories, and other approaches. While much progress has been made in the mechanistic understanding of AD progression, progress in our circuit- and cellular-level understanding of functional deficits and therapeutic benefits *in vivo* has remained particularly challenging. Fully resolving this therapeutic impasse will likely require merging current histology and medicinal

BOX 48.1 (*cont'd*)

chemistry with increased systems-level understanding—through electrophysiology and imaging approaches—of how relevant neural circuits are being modulated pathologically and therapeutically *in vivo* so that our forward progress might be better informed.

as verbal report whenever the memory task requires the explicit expression of memory, as in tests of free recall or recognition memory.

One profoundly amnesic patient, E.P., has a memory impairment and brain damage very similar to that of patient H.M. (Fig. 48.2). Patient E.P. has shown normal performance on a wide variety of nondeclarative memory tasks, despite the fact that his nearly complete anterograde amnesia has kept him from forming conscious memories of the testing situations themselves. For example, in one study, E.P. was shown eight pairs of objects one at a time, each pair containing a correct object and an incorrect object. He slowly learned to pick up the correct object in each pair and after 18 weeks was able to select the correct object almost every time (Bayley, Frascino, & Squire, 2005). When he was asked how he knew which object to pick up, he pointed to his head and replied, "It's here somehow or another and the hand goes for it." In addition to being unavailable to awareness and being very slowly acquired, E.P.'s memory for the objects appeared to lack the flexibility of that shown by healthy individuals, who had learned the task after only three sessions. When the task was changed by presenting all 16 objects together and by asking E.P. to sort them into correct and incorrect piles, his performance deteriorated precipitously. In contrast, healthy individuals performed nearly perfectly on the sorting task. In another study, over the course of 12 weeks, E.P. came to learn a list of 60 three-word nonsense sentences (e.g., "Speech caused laughter."), such that he eventually was able to respond correctly some of the time when asked to fill in the missing third word (e.g., "Speech caused ???"; Bayley & Squire, 2002). Yet E.P. continually expressed surprise when informed that he had seen the sentences previously. On this task, his memory also appeared more rigid than that of control subjects. When the middle word of each sentence was replaced by a synonym, E.P. was able to answer correctly for only one sentence. By contrast, healthy individuals who learned the sentences after only two weeks had no trouble adapting to the new testing format. These studies with patient E.P. illustrate that memory supported by structures outside the hippocampal memory system is not limited to simple and reflexive behaviors, but can be complex and can include acquisition of new verbal information. These studies also highlight the characteristics of memory supported by the hippocampal memory system. Memories formed via the hippocampal system are typically rapidly acquired, flexible, and available to conscious recollection.

Models of Anterograde Amnesia in Experimental Animals

The memory impairment in human amnesic patients has been closely modeled by the performance of monkeys with similar brain damage (Zola-Morgan & Squire, 1985). One key to establishing a model of amnesia in experimental animals was developing tasks suitable for monkeys that would test declarative memory. Figure 48.4 shows two of these memory tasks. Using one of these tasks, researchers found that monkeys with brain damage similar to H.M.'s performed poorly when they had to retain information about objects for more than a few seconds (Mishkin, 1978). Thus, monkeys with medial temporal damage, like humans with amnesia, have intact immediate memory but perform poorly when the memory demand increases over time. In H.M., the damage included the amygdala, the hippocampus, and the surrounding parahippocampal region. Studies in monkeys with restricted lesions to different structures in the medial temporal lobe have shown that the amygdala is not necessary for declarative memory. In addition, the severity of memory impairment depends on the extent and locus of damage within the medial temporal lobe. Damage limited to the hippocampus, or to its major connections through the fornix, produces only a modest impairment. By contrast, damage that includes the parahippocampal cortices produces severe amnesia. Thus, while the hippocampus is a critical component of the system (Zola et al., 2000), the perirhinal and parahippocampal cortical regions also make major contributions to memory. A focus of current research is to better understand the unique contributions of each of the structures within the hippocampal memory system.

Studies in rodents with damage to the hippocampal memory system have also increased our understanding of the functions of the hippocampal memory system.

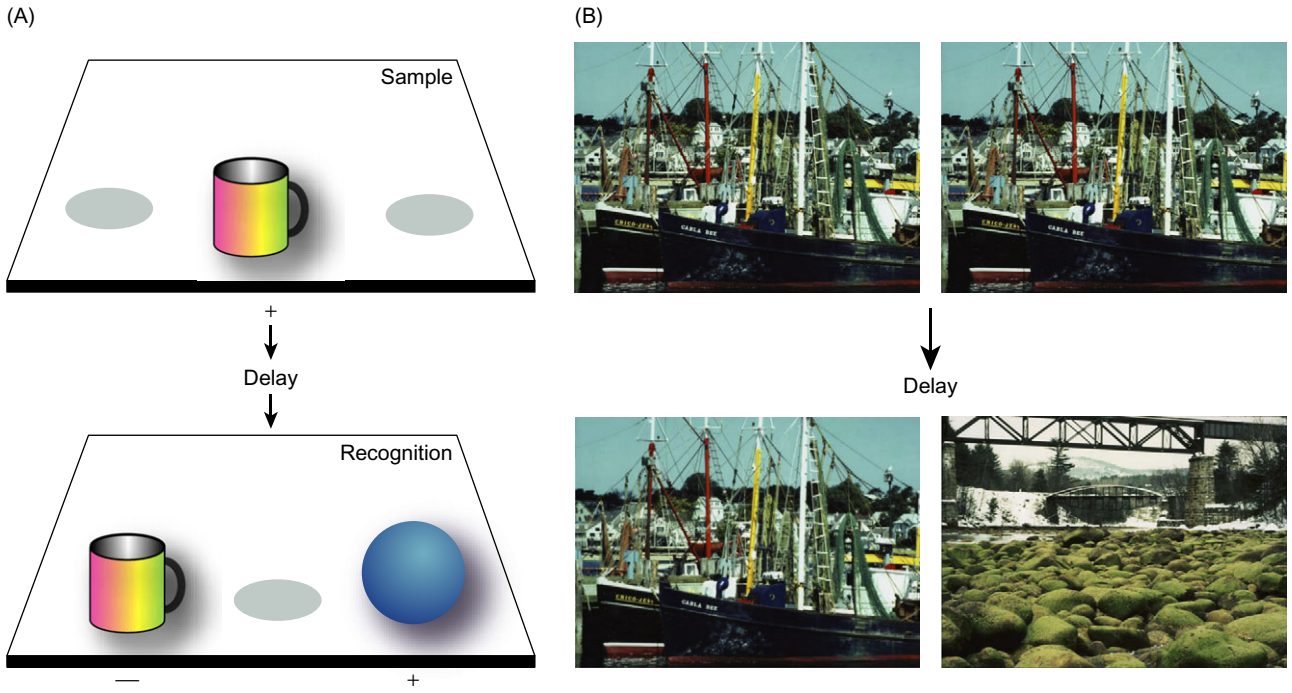

FIGURE 48.4 Recognition memory tasks used for studies of memory in nonhuman primates. Both tasks are easily adapted for human participants as well. (A) The delayed nonmatching-to-sample task using unique objects as stimuli. The subject is initially presented with a single novel object as the sample and must displace the object. This is followed by a variable delay during which the subject cannot see any objects. In the subsequent recognition test, two objects are presented, one of which is the same as the sample and the other of which is novel. Correct performance requires the subject to recognize and avoid the sample object and instead choose the novel one to receive a food reward. (B) Visual paired comparison task. During the sample phase the monkey looks at two identical pictures. In the test phase, one of the sample pictures is represented along with a novel picture. Memory for the repeated picture is inferred by measuring the subject's tendency to look away from the repeated picture and towards the new picture.

Rats with damage to the hippocampus are typically impaired on maze-based tasks when the task depends on memory for space that is capable of being flexibly expressed. One example is place learning in the Morris water maze task (Morris, Garrud, Rawlins, & O'Keefe, 1982; Fig. 48.5). In this task, rats are trained to find a hidden escape platform submerged just below the surface in a pool of cloudy water. The rats are unable to see the platform and must learn the location of the escape site on the basis of cues that are visible on the walls of the room around the pool. Rats with hippocampal damage can learn to locate the escape platform when they start from the same location on every trial. However, their performance is poor when they are asked to demonstrate flexible memory for those spatial relationships by swimming to the remembered location of the submerged platform from a different start point. Consistent with the studies with patient E.P., this pattern of performance reflects a more rigid memory in the absence of a hippocampus.

Other experimental evidence in rats indicates that the hippocampus is also critically involved in the organization and flexible expression of nonspatial memories. For example, in one experiment rats were trained to dig through scented sand to obtain a cereal reward (Bunsey & Eichenbaum, 1996; Fig. 48.6). Initially, both healthy rats and rats with hippocampal lesions learned a set of simple associations between pairs of odors. For example, rats learned to dig in odor B when presented with odor A and to dig in odor C when presented with odor B. Subsequently, the rats were given probe tests to determine the extent to which learned representations supported two forms of flexible memory expression. One of these tests, a test for transitivity, measured the ability to infer an association between two odors that shared a common associate. For example, having learned that odor A is associated with odor B and that odor B is associated with odor C, could they infer that A is associated indirectly with C? The other test, a test for symmetry, measured the ability to recognize associated odors when they were presented in the reverse of their training order. For example, if B is associated with C, is C associated with B? Intact rats showed strong transitivity and symmetry but rats with damage to the hippocampus showed no evidence of transitivity or symmetry. These findings, along with the findings from the water maze and from monkeys, suggest that the hippocampus contributes to rapidly acquired and flexibly expressed spatial and nonspatial memories just as it does in humans.

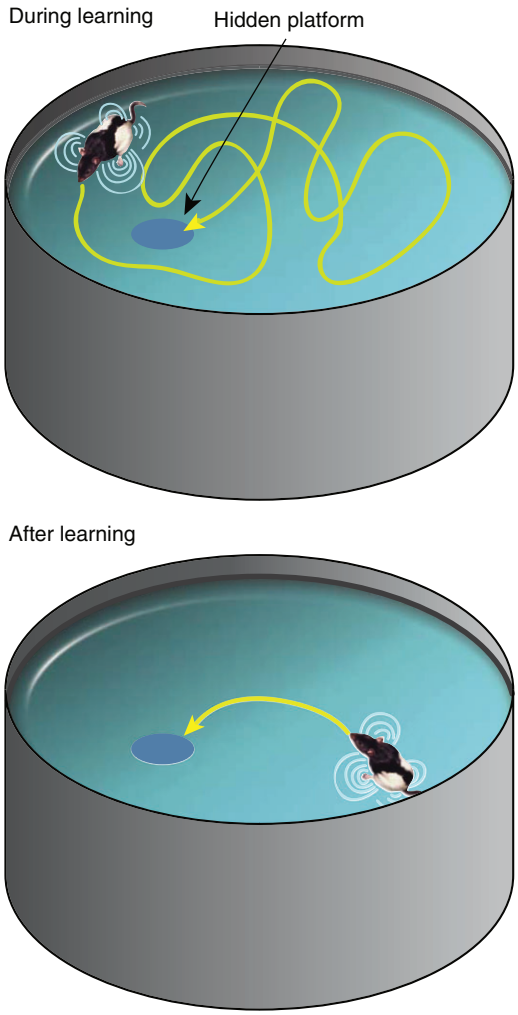

FIGURE 48.5 The Morris water maze task. Early in training, rats search for the submerged platform for extended periods. After training the rat swims directly to the platform.

Neural Activity that Supports Declarative Memory

Studies with humans and experimental animals with damage to the hippocampal memory system have identified the types of memory that depend on the integrity of the hippocampus and parahippocampal region. Complementary studies involving neurophysiological recording and imaging of neural activity in intact medial temporal lobe structures have demonstrated how the hippocampal memory system ordinarily functions in support of declarative memory. In particular, noninvasive functional brain imaging, including functional magnetic resonance imaging (fMRI), has become a key tool for understanding how the hippocampal memory system operates in the intact human brain. In one of the earliest studies, increased activity was observed in the hippocampus and parahippocampal region when participants viewed previously unseen photographs as compared to when participants viewed photographs that they had already seen on multiple occasions (Stern et al., 1996). Subsequent studies found that activity in the hippocampal memory system is often related to the success of memory encoding or retrieval. For example, in one study, participants saw a list of words one at a time while being scanned (Wagner et al., 1998). After the scanning session, participants were given a test to assess which words were remembered and which words were forgotten. The results indicated that activity in the hippocampal memory system during encoding (in this case, in the parahippocampal region) was greater for words that were subsequently remembered compared to words that were forgotten. More recent studies suggest that, in humans, the different cortical areas of the parahippocampal region may play distinct roles in memory, with the perirhinal cortex showing increased activity during the encoding of specific objects and the parahippocampal cortex showing increased activity during the encoding of locations (Buffalo, Bellgowan, & Martin, 2006; Litman, Awipi, & Davachi, 2009; Pihlajamaki et al., 2004). These findings suggest that potential functional differences among medial temporal lobe regions may be linked to distinct neuroanatomical connectivity from nonspatial and spatial processing streams to these regions (Suzuki & Amaral, 1994; Witter et al., 2000).

While neuroimaging studies allow for an identification of neural activity averaged across a few millimeters of brain tissue, intracranial neurophysiological recording techniques allow for an identification of neural activity at the level of individual neurons. Studies in which electrodes were surgically implanted in the brains of monkeys, rats, and even humans (in cases of patients preparing for neurosurgery) have shown that the spiking activity of individual hippocampal neurons corresponds with memory performance on numerous tasks. For example, evidence of novelty and familiarity signals was found in a study of monkeys performing a simple visual recognition memory task (Jutras & Buffalo, 2010), similar to the paired comparison task described above (Fig. 48.4B). Across trials, many hippocampal neurons showed stronger responses to novel stimuli than to repeated stimuli (Fig. 48.7). Further, the magnitude of these firing rate modulations was positively correlated with memory performance. Larger changes in firing rate between novel and repeated stimuli were significantly correlated with better recognition memory performance. Results from human recordings studies also suggest that hippocampal neurons can represent stimulus novelty or familiarity, independent of the specific stimulus (Rutishauser, Mamelak, & Schuman, 2006). Importantly, these results provide evidence linking hippocampal activity with recognition memory performance.

Other studies have shown that hippocampal neurons can demonstrate stimulus-specificity. For example, neurons in the human hippocampus have been shown to fire preferentially for specific categories of images—for

example, faces versus natural scenes (Kreiman, Koch, Fried, 2000) and when the participant viewed or recalled specific video clips (Gelbard-Sagiv, Mukamel, Harel, Malach, & Fried, 2008). Hippocampal neurons in monkeys have been shown to fire preferentially when specific objects (Naya & Suzuki, 2011) or visual scenes were presented to the monkey, and the firing rates of these neurons showed modulations in activity that correlated with the monkeys' ability to learn to move their eyes to a particular place in the scene to receive a reward (Wirth et al., 2003). Studies in rats have also shown that hippocampal neurons sometimes fire preferentially for specific olfactory stimuli as well as combinations of these stimuli and the places where they occur, suggesting that hippocampal neurons represent important stimuli in the context in which they are remembered (Wood, Dudchenko, & Eichenbaum, 1999).

In addition to this activity related to memory for items, neurons with spatial correlates have been identified in the hippocampal memory system of several species of mammals, including humans (O'Keefe & Dostrovsky, 1971; Derdikman & Moser, 2010; also see Chapter 45). In particular, many neurons in the rat hippocampus, referred to as "place cells," have clearly defined spatial receptive fields, or "place fields" (Fig. 48.8A). Activity of these cells reflects the constellation of auditory, olfactory, tactile, and visual cues that define the external world as well as the self-motion cues that track the rat's path through that space. Yet in addition to these clear spatial correlates, activity of these cells also reflects factors such as goals and expectations, and a common view is that the type of spatial memory reflected by place cells in rats shares many commonalities with examples of memory in humans such as recall. Further, cells with location or direction correlates have been found in several regions interconnected with the hippocampus, leading to an understanding of how mental maps might be constructed in the brain. An important advancement in that goal was the identification of "grid cells" in a region of the medial entorhinal cortex, an area reciprocally connected with the hippocampus (Hafting, Fyhn, Molden, Moser, & Moser, 2005). The activity of one of these cells tiles a recording chamber in

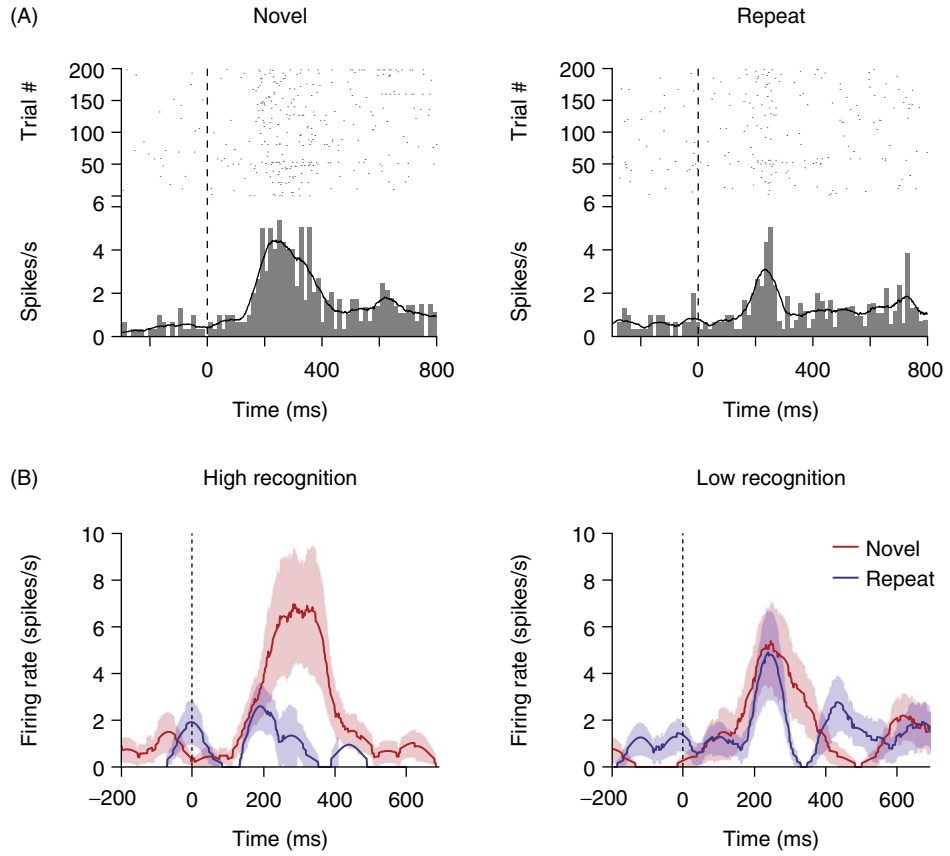

FIGURE 48.7 Recognition memory signals in the monkey hippocampus. (A) As monkeys performed a variant of the Visual Paired Comparison task, some hippocampal neurons showed a change in firing rate that reflected stimulus novelty. This neuron fired more when the pictures were novel (Left panel) compared to when they were repeated (Right panel). (B) Many neurons showed a greater modulation in firing rate by novelty for pictures that were better remembered (Left panel) compared to those that were not well remembered (Right panel). *From Jutras and Buffalo (2010).*

a geometrically regular grid pattern, and the overlapping receptive fields of the population of grid cells in a rat's brain are thought to be an essential component of the rat's mental map (Fig. 48.8B). An important question is how the circuitry of the hippocampus and entorhinal cortex (and other connected areas) enables the transformation of spatial information from a grid field to a place field (and back again). A further question is how nonspatial information is incorporated into these spatial representations to support remembering, for example, which item was encountered in a given location. These questions highlight the distributed nature of memory representations, and the answers could be relevant to general information processing principles in the mammalian hippocampal memory system.

In addition to recording activity of individual neurons, electrode recordings can measure the summed activity of many neurons in the local field potential at a particular recording site (measured either noninvasively from the scalp or with electrodes implanted on the surface or deep in the brain). Using this approach, studies have demonstrated memory-related changes in coordinated network activity that is reflected through oscillations, the synchronized and rhythmic activity of many neurons. Neuronal ensembles often synchronize their activity at a particular frequency band, and oscillatory activity during memory tasks has been observed at theta-band (4 to 12 Hz) and at gamma-band (30–90 Hz) frequencies.

Gamma-band oscillations have been identified in neural recordings taken from patients who volunteered to participate while they were awaiting neurosurgery. In one experiment, patients were asked to study a list of words and subsequently were asked to freely recall as many words as possible. Interestingly, the power of gamma-band oscillations was greater in the hippocampus and parahippocampal regions during the encoding of subsequently recalled words compared to unrecalled words (Sederberg et al., 2007). Using a similar task, others showed that interaction between medial temporal lobe structures might be important for memory formation. In this study, Fell et al. (2001) demonstrated that synchronized activity between the hippocampus and parahippocampal region in the gamma-frequency band was higher during the encoding of subsequently recalled words compared to unrecalled words. Recently, the relationship between gamma-band synchronization and memory formation was extended to single hippocampal neurons. The activity of hippocampal neurons was recorded while monkeys performed a preferential looking task, similar to the visual paired comparison task. Hippocampal neurons showed enhanced gamma-band synchronization during the encoding of pictures that the monkeys later recognized well (Jutras, Fries, & Buffalo, 2009). The time-course of this enhancement was extremely similar in monkeys and humans, using a different behavioral paradigm, which suggests that gamma-band synchronization may reflect a basic mechanism for the neuronal interactions that are critical for successful memory encoding (Fig. 48.9).

Slower, theta-band oscillations are a ubiquitous feature of hippocampal activity in rodents, especially when the animals are actively exploring an environment, and theta-band oscillations have also been described in cats, bats, and even humans. Modulations in theta-band oscillations have also been linked to memory formation (Fuentemilla, Penny, Cashdollar, Bunzeck, & Duzel, 2010; Rutishauser, Mamelak, & Schuman, 2010). For example, Rutishauser et al. (2010) demonstrated that an increase in the tendency of hippocampal neurons to emit action potentials at a consistent phase of the theta-band oscillation was associated with better memory, indicated by higher retrieval confidence in human patients.

Oscillations play an important role in synchronizing activity among neurons within a region or between regions, and recent studies suggest that theta-band and gamma-band oscillations interact to coordinate the flow of information in the hippocampal memory system. For example, gamma-band oscillations have been observed to ride on top of theta-band oscillations, with a single theta wave containing several gamma waves. A recent study in rats found that the troughs of theta waves in CA1 tended

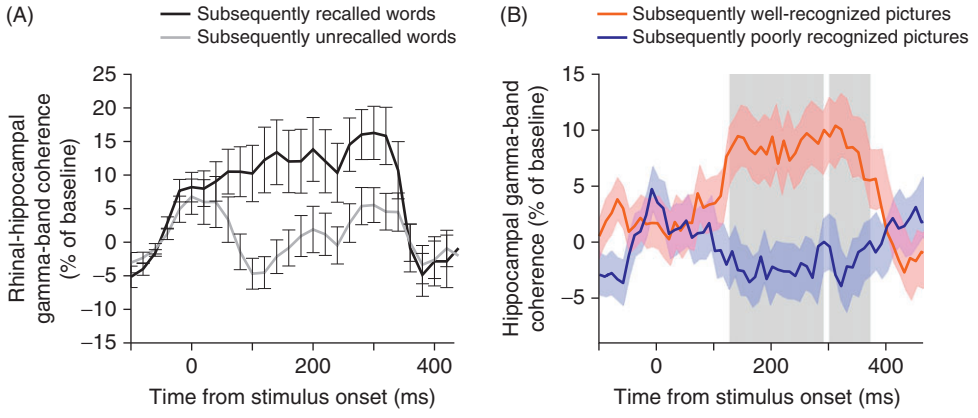

FIGURE 48.9 Gamma-band synchronization in the medial temporal lobe during memory encoding is associated with the degree of subsequent recognition. (A) Gamma-band phase synchronization (coherence) between the human hippocampus and the rhinal cortex during word study, as a function of time from stimulus onset. Coherence was significantly higher during the encoding of words that are subsequently recalled (black) than for words that were not later recalled (gray). Error bars indicate SEM. *Adapted by permission from Macmillan Publishers Ltd. from Fell et al., 2001.* (B) Gamma-band spike-field coherence in the monkey hippocampus during the encoding of pictures, as a function of time from stimulus onset. Coherence was significantly higher for stimuli to which monkeys subsequently showed a high degree of recognition (red) than for stimuli which were not well recognized (blue). Red and blue shaded areas represent SEM. Gray shaded area represents time points at which gamma-band coherence was significantly different for the two conditions ($p < 0.01$). *Modified from Jutras et al. (2009).*

to carry a type of fast (around 65–150 Hz) gamma oscillation also prominent in entorhinal cortex, whereas the downward slope following the peaks of the theta waves tended to carry slow (25–50 Hz) gamma oscillation also prominent in CA3 (Colgin et al., 2009). These results are consistent with the idea that inputs to CA1 from CA3 and entorhinal cortex (Fig. 48.3) are precisely timed by oscillatory activity in the hippocampal memory system in order to optimize memory performance (Hasselmo, Bodelon, & Wyble, 2002; Manns, Zilli, Ong, Hasselmo, & Eichenbaum, 2007). Indeed, action potentials occurring within a single gamma wave that is nested in a theta wave will occur within about 10 ms of each other, a time window that is optimal for synaptic plasticity (Bi & Poo, 1998). Thus, oscillations likely provide the brain with the means to coordinate the activity of large cell assemblies while also optimizing the plasticity within individual junctures of that network.

Transgenic Animals and the Dissection of Hippocampal Circuitry

Experimental animals (typically mice) with modified genes have become another important avenue for exploring the functional circuitry of the hippocampal memory system. Researchers have combined techniques in cell biology with selective breeding to produce transgenic animals that produce too much or too little of targeted proteins in specific parts of the brain. In addition, the altered protein production can be brought under control of drugs that the animals ingest, allowing the timing of the expression of the genetic manipulation to be controlled in addition to the location in the brain. One very fruitful approach to understanding how the hippocampus contributes to declarative memory has been to test the memory of mice that lack a protein important for synaptic plasticity or synaptic transmission in a specific type of cell (e.g., pyramidal cells in hippocampal area CA3). In this way, one can ask how impairing memory at a particular juncture at the synapse level will relate to memory impairments at the systems level. For example, a recent study used sophisticated techniques to produce a strain of mice in which synaptic transmission between CA3 and CA1 hippocampal neurons could be temporarily blocked (Nakashiba, Young, McHugh, Buhl, & Tonegawa, 2008). The combination of memory testing (e.g., in the Morris Water Maze) and neural recording in downstream CA1 pyramidal cells in these mice suggested that the entorhinal cortex input to area CA1 was sufficient for normal acquisition of spatial memory over several trials but that the CA3 input to CA1 was important for single-trial acquisition of spatial memory.

The combination of genetic approaches with animal models of amnesia and neuronal recording has started to sketch some of the roles of the structures within the hippocampus. Two important aspects of memory that have been proposed to differentially involve the dentate gyrus, CA1, and CA3 subregions of the hippocampus are termed "pattern separation" and "pattern completion." Pattern separation refers to the process of distinguishing between two similar inputs and storing them as separate representations. By comparison, pattern completion refers to the process of filling-in partial or incomplete sensory input based on stored representations. There is accumulating experimental evidence and computational theory to support the idea that the dentate gyrus input to CA3 is a particularly important pathway for pattern separation, while CA3 neurons combine input from the dentate gyrus, the entorhinal cortex, and their own recurrent collaterals and project to CA1 in the process of pattern completion (Rolls, 2010; Yassa & Stark, 2011).

Retrograde Amnesia and Consolidation

So far, this chapter has focused primarily on the structures and neural signals that support the formation of new memories. However, patients with amnesia due to medial temporal lobe damage suffer not only a deficit in learning new material (anterograde amnesia), but also loss of memories that were acquired before the brain damage (retrograde amnesia). Importantly, the retrograde deficit is time-limited, and material acquired shortly before the damage is affected most severely, whereas items learned earlier in life are relatively spared. For example, the profoundly amnesic patient E.P. (Fig. 48.2) has almost no capacity for new declarative learning but shows intact memories from his childhood. In one study, E.P. was asked to think back to his childhood neighborhood and describe routes he would take from one location to another (e.g., his grade school to the town movie theater; Teng & Squire, 1999). In some instances, he was asked to imagine that a main street was blocked and to describe an alternate route. E.P. performed as well as a group of healthy individuals who had lived in the neighborhood at the same time and, like E.P. had moved from the area as young adults, long before the study. These data indicated that his memory for the spatial layout of his childhood neighborhood had escaped the damage to his medial temporal lobes. Consistent with his severe anterograde amnesia described earlier in this chapter, E.P. has been unable to learn the layout of the neighborhood he moved to subsequent to the onset of amnesia.

Retrograde amnesia is another aspect of the amnesic syndrome that has been studied in experimental animals. For example, studies have shown that simple object discriminations that were learned by monkeys shortly before medial temporal lobe damage are poorly retained, but discriminations learned remotely are spared. This pattern of memory impairment has been replicated in a variety of tasks in humans, monkeys, rabbits, rats, and mice and is thought to reflect a process of memory consolidation (Squire, Clark, & Knowlton, 2001).

The term *consolidation* has been used to characterize two kinds of brain events that affect the stability of memory after learning. One event involves the fixation of plasticity within synapses over a period of minutes or hours through a sequence of protein synthesis and morphological changes at synapses (see Chapter 47). The other event involves a reorganization of memories, which occurs over weeks to years following new learning. This prolonged consolidation occurs in the hippocampal memory system and is thought to involve interactions between the hippocampus, parahippocampal region, and the cerebral cortex. Several models have been proposed to account for how the hippocampus might interact with other brain regions over a prolonged period in memory consolidation (Alvarez & Squire, 1994; McClelland, McNaughton, & O'Reilly, 1995). These models assume that widespread areas of the neocortex contain the details of the information that is to be remembered and that areas in the hippocampal memory system support the capacity to retrieve the memory during the period shortly after learning. Over time, areas in the hippocampus are thought to reactivate the cortical representations through repetition, rehearsal, or spontaneous activity. The reactivation is then thought to induce plasticity in cortical-cortical connections, and these connections are viewed as a possible network structure for the permanent storage and organization of the memory. In support of this idea, it was recently demonstrated that activity in the neocortex could predict the recall of specific memories. Polyn, Natu, Cohen, and Norman (2005) asked human subjects to first study three lists of items including photographs of famous faces, famous locations, and common objects. Subsequently, the subjects performed a free-recall test where they were asked to recall as many items from the study lists as possible. Functional MRI was used to examine neural activity during both the study episode and the free-recall period, and the data revealed patterns of activity immediately prior to the recall of specific items that were similar to activity observed as the subjects studied that category of items (e.g., faces vs. locations or objects).

Recent studies using molecular markers of neuronal activity and synaptic change have also reported evidence consistent with this idea. For example, one study of maze learning in mice observed that these markers were found in high numbers in the hippocampus one day after learning but their numbers were much lower 30 days later (Maviel, Durkin, Menzaghi, & Bontempi, 2004). By contrast, the same markers were found at low levels in the cerebral cortex initially after learning but were high in various cortical areas 30 days after learning; cortical areas included the prefrontal, anterior cingulate, and retrosplenial cortices. These results suggest that plasticity in the hippocampus is initially important for memory formation, but over time, plasticity in neocortical areas becomes more important.

There has long been interest in the role of sleep and dreaming in memory, and it has been suggested that processes might occur during sleep that promote the consolidation of hippocampus-dependent memories. Although the benefit of sleep for nonconscious learning is generally accepted, the status of hippocampus-dependent memory is less certain (Stickgold, 2005). Nevertheless, there are several results that indicate that processes during sleep might contribute to consolidation of hippocampus-dependent memory. For example, specific patterns of activity observed in the hippocampus while rats were awake were observed to "replay" during both REM sleep and slow wave sleep (Sutherland & McNaughton, 2000). Later studies linked hippocampal replay to sharp wave ripples (SWRs). SWRs are prominent during sleep and are recorded in the CA3 and CA1 regions as a transient (~100 ms) high-frequency oscillation (100–250 Hz). During SWRs, activity propagates from CA3 to CA1, and then out to the neocortex. This hippocampal-cortical interaction may be important for consolidation, and studies suggest that reactivation of memories during sleep may participate in the process of consolidation. SWRs occur also during the waking state, and hippocampal replay has been recently observed during SWRs as rats explored a novel environment. Interestingly, awake replay is more prevalent and temporally precise when rats are learning a novel environment, compared to when they are placed in a familiar environment (Diba and Buzsaki, 2007; Foster and Wilson, 2006). SWRs occur most often during slow-wave sleep, and another study showed that induction of slow-wave-like oscillations in the brains of human participants while they slept led to better retention in that less forgetting occurred across the interval (Marshall, Helgadottir, Molle, & Born, 2006). Thus, there is accumulating evidence regarding the role of sleep in the consolidation of hippocampus-dependent memory, but further work is needed to fully understand this process.

Summary of Hippocampus

Amnesia associated with damage to the hippocampal memory system in humans is characterized by an inability to form and consciously recollect memories of facts and events. Studies with animal models of amnesia have furthered our understanding of the function of the hippocampus and the parahippocampal region. Neurophysiological and neuroimaging studies have provided insight into the neural activity that may underlie declarative memory formation. Taken together, data obtained from a variety of techniques have indicated the importance of interactions within the hippocampal memory system as well as between the hippocampal memory system and the cerebral cortex in the formation and consolidation of declarative memories.

Striatum

Anatomy

The striatum is an important component of the basal ganglia (see Chapter 30), and its position within a distributed cortico-basal ganglia network is central to its function as a hub of a memory system. Sensorimotor, associative, and limbic cortical areas project to specific regions of the striatum (dorsolateral, dorsomedial, and ventral regions, respectively), and outputs of these regions loop through the pallidum to gain access to brainstem structures and back to cortical areas via the thalamus (Fig. 48.10). In addition, the striatum receives modulatory inputs from dopaminergic cells in the midbrain. Thus, the striatum receives information relevant to actions, external stimuli, and internal states (including expectations) and can influence behavior via brainstem pathways or by updating processing in cortical areas. See Chapters 30 and 41 for additional consideration of the role of the striatum in motor control and in reward and motivation, respectively.

Identifying Memory Supported by the Striatum

Early efforts to understand the role of the striatum in memory often sought to distinguish its contributions from those of the hippocampal memory system. For example, one study compared performance on a simple T-shaped maze between rats with pharmacological inactivation of the hippocampus or dorsal striatum (Packard & McGaugh, 1996). During training, neither structure was inactivated, and all rats learned to run to a consistent choice arm (e.g., left for some rats) for a food reward when started at the base of the T-maze. During testing, the T-maze was rotated 180 degrees, and the question was whether a rat would continue to make left turns at the choice point (if it had been trained to run to the left arm), indicating memory resembling a habitual response ("response" memory), or would now make right turns, indicating a more flexible memory for the location of the food reward relative to the surrounding room ("place" memory; Fig. 48.11). The finding was that, after a week of training, most rats showed evidence of using place memory. Furthermore, inactivating the striatum during the test had little effect on performance, but inactivating the hippocampus led some rats to shift to a strategy that suggested the rats were compensating with response memory. Following the initial test, the T-maze was rotated back to its original position, and all rats received another week of training during which neither structure was inactivated. After this second week of training, the T-maze was again rotated 180 degrees, and the results on the second test differed substantially from the first. Most rats now showed evidence of relying on the response memory, and inactivation of the hippocampus had little effect on performance. Instead, inactivation of the striatum led many rats to alter their performance and again resort to place memory. These results suggested that, after initial training, performance normally relied on a memory for the location of the food that was flexible enough to be accessed despite rotation of the maze and that this type of place memory depended on the hippocampus. However, after more extended training, performance appeared to come under influence of a habitual response memory that depended on the striatum.

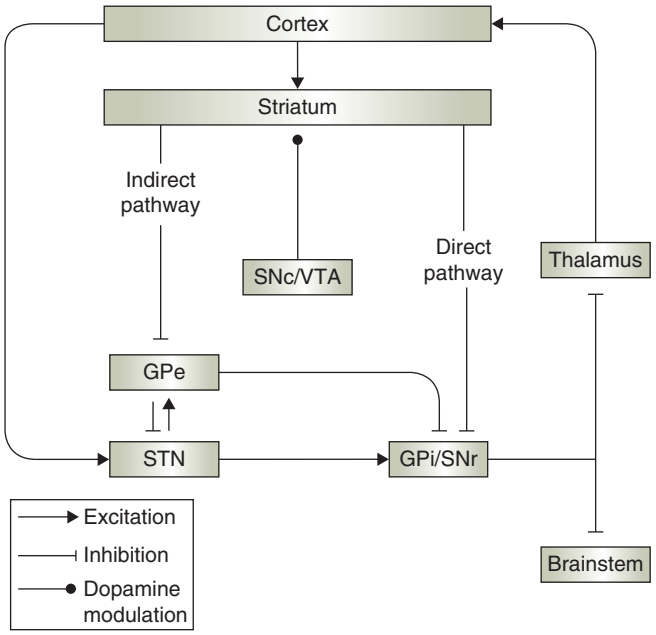

FIGURE 48.10 Anatomy of the striatum and the rest of the basal ganglia. STN, subthalamic nucleus; GPe, external globus pallidus; GPi, internal globus pallidus; SNr, substantia nigra pars reticulata; SNc, substantia nigra pars compacta; VTA, ventral tegmental area. *From Yin and Knowlton (2006).*

These early results with rats were paralleled by a study that compared memory between amnesic patients with damage to the extended hippocampal memory system and patients with Parkinson's disease (Knowlton, Mangels, & Squire, 1996), a disease that disrupts striatal function through degeneration of dopaminergic inputs from the substantia nigra. Both groups of patients and a group of healthy individuals were tested on a task in which they tried to guess on each trial whether the stimulus cards presented to them foreshadowed rain or sunshine (Fig. 48.12). The cards predicted rain or sunshine only in a probabilistic manner, and healthy individuals improved their performance from 50% (guessing) to about 70% only after 50 trials. Thus, the predictive value of the cards did not appear to be easily memorized, and performance instead appeared to rely on slowly acquired trial-and-error learning. Patient's with Parkinson's disease showed little improvement over the 50 trials, but amnesic patients performed about as well as the healthy individuals. In contrast, when the participants were subsequently asked questions about the nature of the task and the kinds of materials they

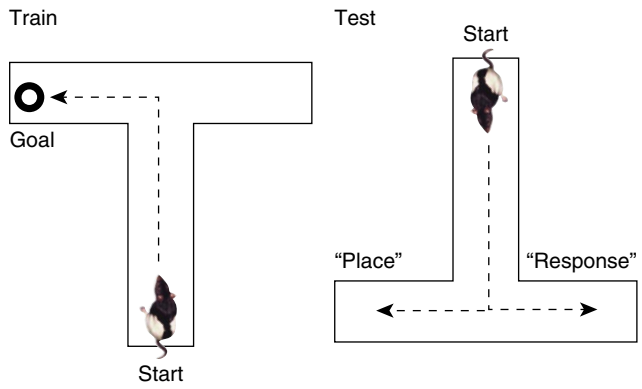

FIGURE 48.11 "Place" versus "response" learning. The rat is trained initially to turn left in order to obtain a reward at a particular location. In a subsequent test, the maze is rotated and the rat is allowed to select whether it will perform the same left turning "response" or remember the "place" of the previous reward.

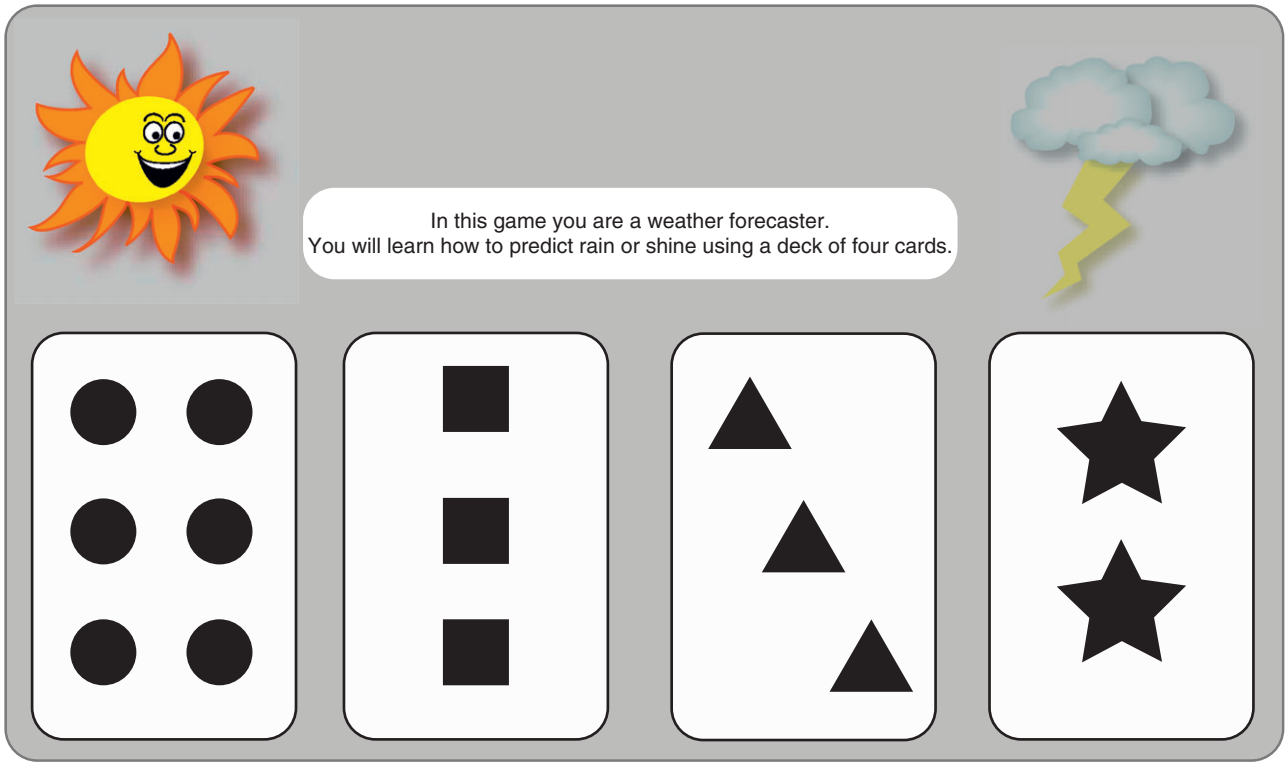

FIGURE 48.12 Weather prediction task. View of the computer screen presented to subjects showing all four stimulus cards and the "sun" or "rain" response choices. *From Knowlton et al. (1996).*

had encountered, the patients with Parkinson's disease performed as well as controls, and the amnesic patients showed very poor memory. Thus, results with humans agreed with results from experimental animals in suggesting that the striatum was part of a memory system that was distinct from the hippocampal memory system.

Memory for Actions, Outcomes, and Habits

These initial studies suggested that the striatal memory system accumulated trial-and-error experiences as inclinations to make certain responses in the presence of particular stimuli and that these inclinations differed from the record of individual experiences supported by the hippocampus. Nevertheless, these studies also suggested that the memory supported by the striatum was too complex to be described fully as simple stimulus-response learning. Indeed, more recent research has investigated how the striatal memory system incorporates outcomes of individual actions into the stimulus-response association and how its initial participation in evaluation and decision making might give way to a role in habit-like responding with extended training.

Studies in which the activity of midbrain dopamine neurons was recorded have provided some clues about how consequences of actions could be incorporated into memory supported by the striatum (Schultz, 2007). These studies have indicated that these midbrain dopamine neurons increase their firing in response not only to rewards but also to secondary cues that predict the delivery of those rewards. In addition, these neurons also appear to signal a mismatch between expected outcome and actual outcome by, for example, an exaggerated response when an unexpected reward was delivered. Thus, the projections into the striatum from these midbrain regions could help to update inclinations or disinclinations to engage a particular response in the presence of particular stimuli based on whether the previous response was rewarded with a favorable outcome.

In addition, studies that have recorded activity in the striatum in both humans and experimental animals have indicated that the striatum likely incorporates these anticipated outcome signals (Graybiel, 2008). For example, a study in which neurons were recorded from the striatum as rats performed a more elaborate version of the T-maze task found that both the dorsal and ventral striatum were engaged at moments when a turning response was to be made but that the contributions of these regions seemed to differ according to whether it was early or late in training (van der Meer, Johnson, Schmitzer-Torbert, & Redish, 2010). In particular, some neurons from the ventral striatum showed increased activity at one of two possible reward locations (i.e., left or right). Some of these reward-related neurons also showed activity early on in training when the rat paused at a point on the maze when the rat needed to choose to turn left or right. Thus, early on in training, the ventral striatum appeared to gain access to prior favorable outcomes in selecting an action to perform in the same scenario again. In comparison, neurons in dorsal striatum showed increased activity unrelated to reward at turns on the maze and did so with more spatial accuracy later on in sessions. These results are consistent with the idea that striatal learning typically progresses from a probing action selection to a habitual response and that this deemphasizing of the outcome parallels a reorganization from a network centered on the ventral striatum to a network more centered in dorsal striatum. This idea has been extended to habits of many kinds, including drug addiction and other compulsive behaviors (see Chapter 41).

Summary of Striatum

The striatum is a key structure in a distributed cortico-basal ganglia memory system that supports the acquisition of inclinations to make specific responses in particular situations. The striatum contributes to an initial evaluative action-outcome learning and to a habitual stimulus-response learning after extended training. Recent results suggest that the ventral striatum might be particularly important for the former and that the dorsal striatum might be particularly important for the latter.

Cerebellum

Anatomy

The cerebellum consists of the cerebellar cortex, which has been divided into lobes and further into lobules, and several deep cerebellar nuclei (see Chapter 31 for more detailed anatomy). The cerebellum receives direct input from the spinal cord and brainstem as well as indirect input from a variety of sensory and motor areas in the cerebral cortex via pontine nuclei in the brainstem. The cerebellum projects directly to the spinal cord, brainstem, hypothalamus, and thalamus, and the thalamic targets in turn project to various motor and nonmotor areas in the cortex, particularly in the frontal lobes (Middleton & Strick, 1998). The internal circuitry of the cerebellum has been described as modular, with a local wiring diagram that is repeated again and again. This modularity raises the possibility that, although different regions of the cerebellum receive different input, each region might perform a similar set of operations on that information before passing the results back out to the rest of the nervous system (Boyden, Katoh, & Raymond, 2004).

Eyeblink Classical Conditioning as a Prototype of Cerebellum-Dependent Memory

The cerebellum is important for a range of sensorimotor functions, including adaptations of the vestibulo-occular response and coordinated motor skill learning. The cerebellum has also been associated with nonmotor learning and other examples of cognition and behavior. The present section focuses on the best-understood example of cerebellar-dependent learning, eyeblink classical conditioning, as a framework for highlighting the role of the cerebellum in memory based on the idea that the modular circuitry of the cerebellum offers a generalized capacity for processing of specific inputs.

In standard "delay" eyeblink classical conditioning, a conditioned stimulus (CS; e.g., a brief tone) is initiated immediately (typically a second or less) prior to the delivery of an unconditioned stimulus (US; e.g., a brief puff of air to the eye), and both stimuli then terminate at the same time. The US triggers a reflexive, unconditioned eyeblink (the UR), and after many pairings of CS and US, the CS eventually elicits an eyeblink as a conditioned response timed such that the blink is most robust at the US onset. Remarkably, rabbits with no cerebral cortex, basal ganglia, limbic system, thalamus, or hypothalamus showed normal retention of the conditioned eyeblink response (Mauk & Thompson, 1987), indicating that no forebrain structures

were an essential part of the neural circuitry supporting standard eyeblink conditioning.

Numerous studies by Thompson and colleagues have traced the paths to the cerebellum taken by incoming sensory information about the CS and the US and have found that these paths converge on one particular cerebellar nucleus, the interpositus nucleus, and that outputs of this nucleus have a clear route to producing conditioned eyeblink responses (Fig. 48.13; Thompson, 2005). These experiments were able to capitalize on the well-defined circuitry to show that the interpositus nucleus was a locus of plasticity essential for acquiring and retaining a CS-US association capable of supporting conditioned blinks in response to the CS in a manner that was dissociable from the ability to emit unconditioned blinks in response to the US. Additional studies have indicated that the cerebellar cortex is an important part of the circuitry for modulating the timing of the conditioned response to ensure that it is adaptive.

Delineation of the functional circuitry of eyeblink classical conditioning, along with results from other paradigms and from computer simulations, has provided a view of the cerebellum and as a key part of a circuit capable of finely recalibrating the sub-second timing of outputs based on the precise timing of inputs (Ohyama, Nores, Murphy, & Mauk, 2003). By this view, the "error" signal of a puff of air to an open eye is used to recalibrate the timing of an eyeblink with the help of the predictive value of the CS so that the next puff might be received by a closed eye. The capacity of the cerebellum and associated circuitry to recalibrate sub-second timing may contribute in a similar manner to other examples of learning, such as in the recalibration of the timing of contraction of opposing arm muscles in executing coordinated reaching movements such that a missed object can be successfully grasped.

Summary of cerebellum

The circuitry essential for eyeblink classical conditioning has been identified and provides an experimentally tractable opportunity to investigate what may be generalized learning processes supported by the cerebellum. These processes may contribute generally to recalibrating the timing of outputs in sensorimotor learning or even more generally to mental processing involved in precise timing.

Amygdala

Anatomy

Two major areas of the amygdala involved in emotional memory are the basolateral complex of the amygdala (BLA; includes the lateral, basolateral, and basomedial nuclei) and the central nucleus of the amygdala (CEA; Fig. 48.14B). The BLA receives input from widespread cortical areas as well as from sensory nuclei of the thalamus and thus has access to higher-level information from association areas as well as lower-level sensory information. In addition, the BLA has reciprocal connections with other

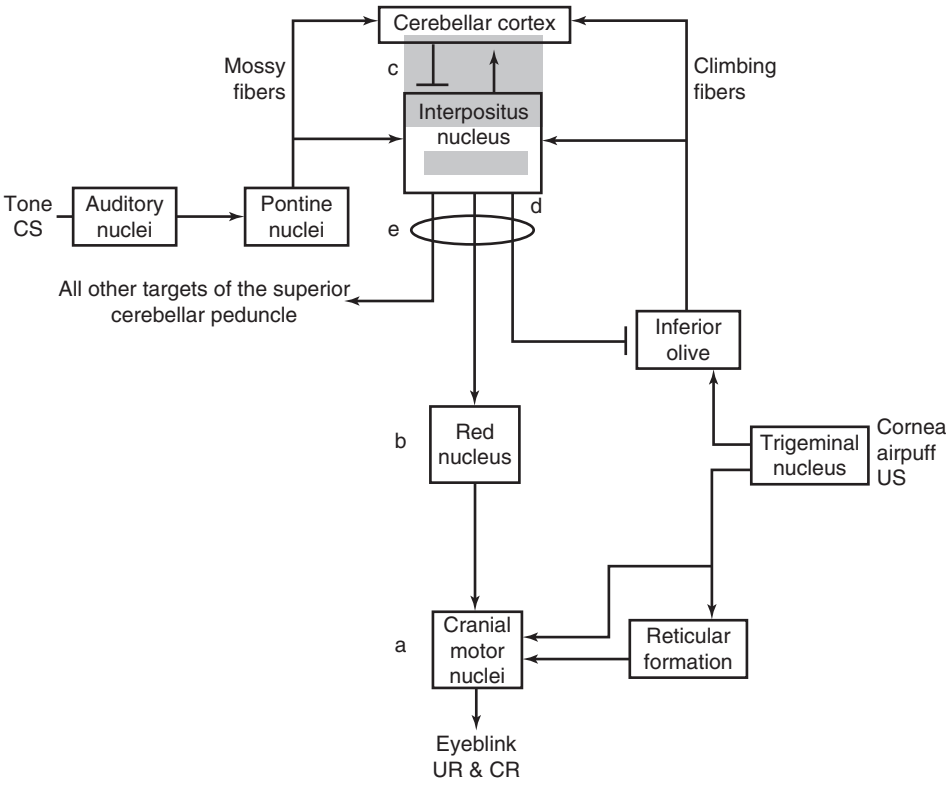

FIGURE 48.13 A schematic diagram of principal pathways involved in classical conditioning of the eyeblink reflex. The role of structures at points a–e has been studied using reversible inactivation with a local anesthetic. Inactivation at point "c" (shaded areas) prevents learning, whereas inactivation at "a," "b," "d," or "e" prevents the behavioral response during inactivation, but does not block learning. *From Thompson and Kim (1996).*

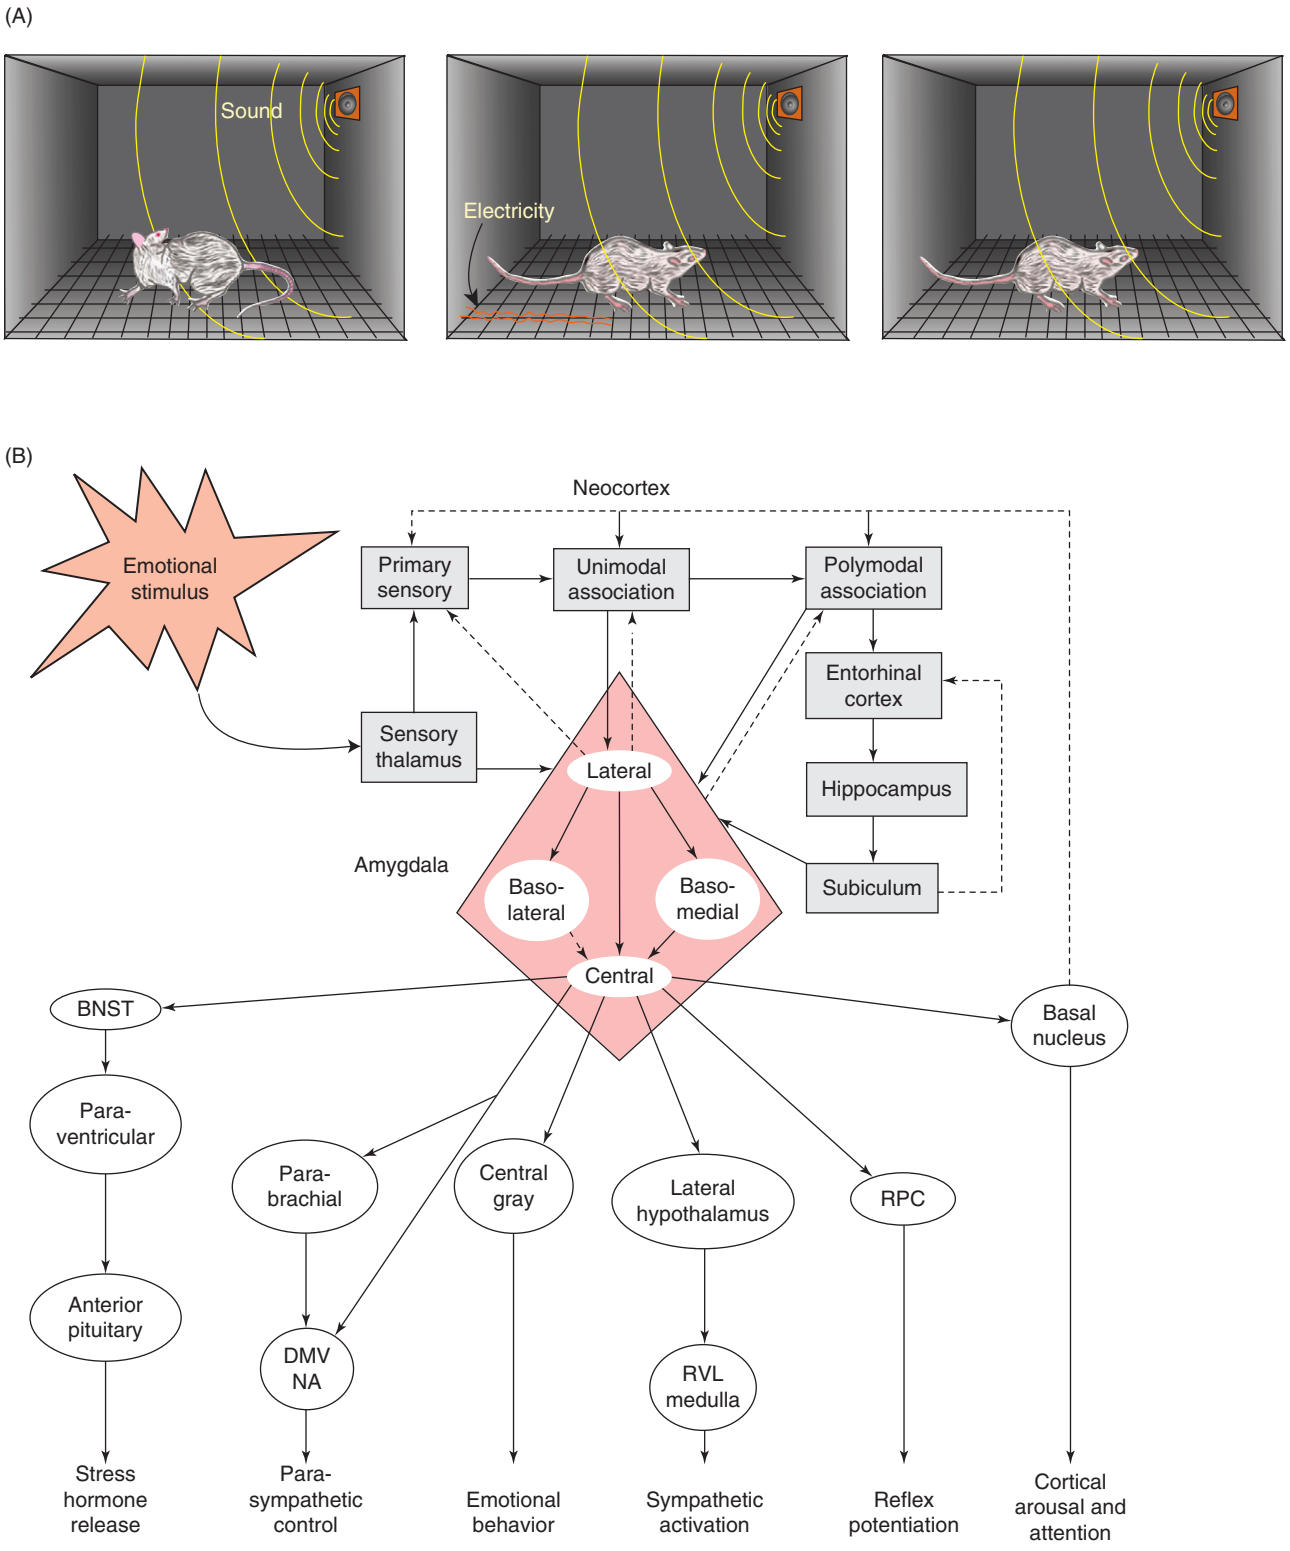

FIGURE 48.14 Fear conditioning. (A) Prior to training, the tone produces a transient orienting response. During training the tone is followed by a brief foot shock. Following training, the rat is reintroduced into the chamber and freezes when the tone is presented. (B) Anatomical pathways that mediate fear conditioning. A hierarchy of sensory inputs converges on the lateral amygdala nucleus, which projects to other amygdala nuclei and then to the central nucleus, which send outputs to several effector systems for emotional responses. BNST, bed nucleus of the stria terminalis; DMV, dorsal nucleus of the vagus; NA, nucleus ambiguus; RPC, nucleus reticularis pontis oralis; RVL, rostral ventral nucleus of the medulla. *From LeDoux (1995).*

brain systems, including the hippocampal and striatal memory systems. Areas within the BLA project to the central nucleus, which is the source of outputs to subcortical areas controlling a broad range of fear-related behaviors, including autonomic (e.g., changes in heart rate, blood pressure, sweating, or hormone release) and motor responses (e.g., fear-related freezing behavior).

The amygdala contributes to emotion in several ways, including mediating emotional influences on attention and perception and regulating emotional responses (Phelps & LeDoux, 2005). The topic of the present section is the two ways in which the amygdala contributes to emotional memory. First, the amygdala supports the acquisition of emotional dispositions towards stimuli. Second, the amygdala mediates the influence of emotion on the consolidation of memory in other memory systems.

Role of the Amygdala in Acquiring Emotional Dispositions to Stimuli

A particularly productive approach to studying the role of the amygdala in memory has been to focus on the circuitry that supports acquisition of fearful responses to simple auditory or visual stimuli (Fanselow & Gale, 2003; Lang & Davis, 2006; Paré, Quirk, & Ledoux, 2004). In one frequently used task (Fig. 48.14A), rats are initially habituated to a chamber and are then presented with multiple pairings of a tone (the CS) that terminates with a brief electric shock delivered through the floor of the chamber (the US), which typically results in an unconditioned jumping response (the UR). Subsequently, conditioned fear elicited by the tone is assessed by measuring autonomic responses or motor responses (the CR), such as freezing behavior. Rats with lesions in the BLA show markedly reduced conditioned fear responses to the tone but still show normal unconditioned fear responses to the shock itself. Rats with lesions to the central nucleus show reduced fear responses to both conditioned and unconditioned stimuli. Thus, the BLA appears to be important for acquiring an aversion to the tone, whereas the central nucleus appears to be additionally important for producing fearful responses in general.

A study in which fear conditioning was adapted for use in patients with damage to the amygdala or the hippocampus verified that the amygdala is crucial for acquiring conditioned fear responses and found further that these learned aversions are independent of declarative memory for the learning event (Bechera et al., 1995). In addition, functional imaging studies in healthy individuals have found increased activity in the amygdala for both positive and negative stimuli as compared to neutral stimuli (Vytal & Hamann, 2010), consistent with the view from experimental animals that, although its involvement in fear learning may be especially robust, the amygdala is important for acquiring both aversions and preferences to previously neutral stimuli (Morrison & Salzman, 2010).

Similar to the example of eyeblink classical conditioning and the cerebellum, identifying the confluence of CS and US pathways in the amygdala has provided opportunities for exploring the neurobiological details of emotional memory at a key locus of plasticity. These opportunities are also relevant to mental health issues including anxiety, phobias, and post-traumatic stress disorder, and a recent area of interest in emotional memory has been how the brain supports relearning that a stimulus no longer predicts a fear-inducing outcome (Jovanovic & Ressler, 2010). These studies suggest that the medial prefrontal cortex may play an important role by inhibiting activity in the amygdala in order to suppress previously learned fear responses and by mediating plasticity so that a new non-fearful disposition can be associated with the stimulus (Quirk & Mueller, 2008; Quirk et al., 2010).

Role of the Amygdala in the Modulation of Memory

Emotion can enhance memory, and evidence from a large number of studies in experimental animals has indicated that the amygdala, in particular the BLA, mediates this memory enhancing effect (McGaugh, 2004). In particular, emotionally arousing events result in the release of epinephrine and glucocorticoids by the adrenal glands, which in turn result in the release of norepinephrine in the amygdala (Fig. 48.15). The release of norepinephrine

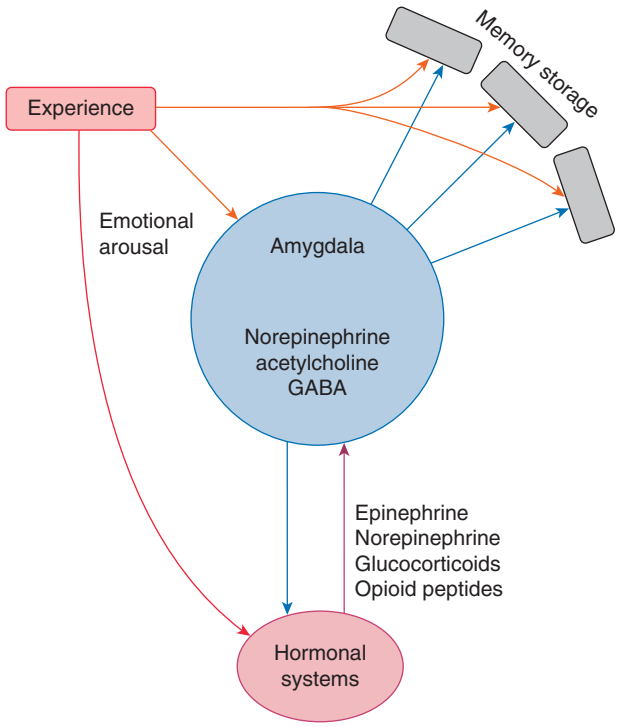

FIGURE 48.15 A schematic representation of how hormonal systems and the amygdala complex can modulate the storage of memory for emotionally arousing events through influences on other brain systems. See text for details. *From McGaugh, Introini-Collison, Cahill, Kim, and Liang (1992).*

leads to an increase in activity in the amygdala, which is thought to influence consolidation of memory in the other parts of the brain, either directly, through connections of the amygdala with the striatum, hippocampus, and cortex, or indirectly, through connections with nucleus basalis (which innervates much of the cortex). Data in support of this model include the findings that damage to the BLA or infusions of drugs in the BLA that interfere with norepinephrine block the memory enhancing effect of emotional arousal. In addition, infusion of norepinephrine directly into the BLA following a learning session can enhance subsequent memory, even in instances such as object recognition memory in which emotional arousal ordinarily does not make an essential contribution to the memory (Roozendaal, Castello, Vedana, Barsegyan, & McGaugh, 2008). Furthermore, the modulatory influence of the BLA seems to be limited to the time of the learning event as well as a short period of time after. Manipulations of the amygdala during subsequent testing of retention typically do not influence memory performance. Thus, the amygdala is important in modulating storage in emotionally stressful situations, but not in the maintenance or retrieval of the memory that has been modulated.

The amygdala has been strongly implicated in the enhancement of memory for emotional material in humans as well as in experimental animals. In one study, a patient with damage to the amygdala was tested for memory of an emotional story along with a group of healthy individuals (Adolphs, Cahill, Schul, & Babinsky, 1997). The participants watched a series of slides and listened to an accompanying narrative that told a story about a mother and son. One portion of the story involved a traumatic accident, and all participants rated this portion as being strongly emotional. Compared to the healthy individuals, the patient with damage to the amygdala failed to show enhancement of memory for the emotional part of the story. However, the patient performed as well as others on neutral story material. In brain imaging studies with healthy individuals, the amygdala was activated during the viewing of emotional material that elicited either positive or negative emotional reactions, and this activation was related to the likelihood that participants were able to subsequently remember the emotional material (Cahill et al., 1996; Canli, Zhao, Brewer, Gabrieli, & Cahill, 2000; Hamann, Ely, Grafton, & Kilts, 1999). In these studies, there was no correlation between activation of the amygdala and subsequent memory performance for neutral material.

Summary of Amygdala

The amygdala is well situated anatomically to attach emotional (positive and negative) dispositions to a broad range of stimuli and to mediate the acquisition of such dispositions in the absence of conscious recollection of the circumstances of the emotional experience. In addition, components of the amygdala also mediate the modulation of memory storage during and after emotional events. These two roles in memory could be brought together in situations in which, for example, a conditioned fear response to a stimulus leads to emotional arousal and to modulation of declarative memory for the event.

Cerebral Cortex

Anatomy

The posterior half of the cerebral cortex contains many functionally distinct areas that are organized into hierarchies of serial and parallel processing for each sensory modality (see Chapter 2). The anterior cerebral cortex contains a similar hierarchy of motor areas, as well as association areas in the prefrontal cortex involved with motor planning, higher order cognition, and working memory (Fuster, 2001; see Chapter 50). Additionally, information from different modalities converges on "association" areas in the parietal and temporal lobes.

Some of the examples provided so far, such as standard eyeblink classical conditioning, illustrate that some simple forms of learning can circumvent the cerebral cortex. Nevertheless, for all the memory systems discussed in this chapter, including the cerebellum, the cerebral cortex provides important access to incoming information as well as output routes to influence behavior. Yet plasticity in the cerebral cortex also directly supports types of memory that do not require components of the other memory systems. For each area of the cortex, the modification of its information processing circuitry through alterations in synaptic connectivity and membrane excitability underlies its direct participation in memory. These alterations can be dramatic, such as in examples of experience-dependent reorganization that occurs in perceptual or motor learning, but can also be more subtle, such as in the phenomenon of repetition priming.

Perceptual and Motor Learning

Extended experience with a particular set of stimuli or particular set of movements can result in the modification of the cortical areas important for perceiving those stimuli or executing those movements. In particular, studies in a variety of experimental animals have used single-neuron recordings to identify the stimulus-selectivity or movement-selectivity of individual neurons and to map their location in the cortex. A common finding in these studies is that training on a particular perceptual or motor task, such as a fine-grained auditory or tactile discrimination or a skilled reaching task, leads to an increase in the area of the cortex containing neurons that are selective for the stimuli or movements used in the task (Buonomano &

Merzenich, 1998; Monfils, Plautz, & Kleim, 2005; Weinberger, 2007). In some of these studies, cortical changes were correlated with task performance, suggesting that these cortical alterations were an important part of the acquired memory.

Functional imaging studies in humans have also suggested that the cortical areas important for perceiving the stimuli or executing the actions are also important areas of plasticity. For example, in one study participants were scanned while viewing pictures of nonsense objects both before and after performing a perceptual discrimination task that included half of the objects (Op de Beeck, Baker, DiCarlo, & Kanwisher, 2006). Following the perceptual discrimination task, the pattern of brain activity in object-responsive areas in visual cortex had changed for the objects included in the discrimination task but did not differ for the objects not included in the discrimination task. Thus, it appears that many of the areas in the cerebral cortex that are specialized for specific perceptual or information processing functions—from areas involved in perceiving simple tones to areas involved in perceiving complex objects—are capable of supporting perceptual learning for those stimuli.

Repetition Priming

Another example of memory thought to be supported directly by the cerebral cortex is the phenomenon known as repetition priming (or priming). Priming involves repeating previously presented items, either unaltered or as fragments of the original (e.g., word fragments or briefly flashed pictures), and measuring the increased fluency with which those items are identified as compared to items not repeated. For example, in one task, repeated and unrepeated words are flashed on a screen so briefly that many of the words are unreadable, and the measure of priming is the increased likelihood of identifying repeated words as compared with unrepeated words. Studies with amnesic patients and healthy individuals have found that successful priming is typically independent of the ability to recognize which items were repeated (Stark & Squire, 2000). Further, functional imaging studies in healthy individuals suggest that priming often results in reduced activity in cortical areas involved in initially processing the stimuli (Schacter, Wig, & Stevens, 2007), suggesting that less neural activity is required to identify words recently processed. These findings suggest that the neuronal basis of priming is an increase in the efficiency and bias in the direction of cortical sensory processing associated with perceptual identification.

Summary of Cerebral Cortex

The cerebral cortex provides a major route of information flow into and out of all of the memory systems discussed in this chapter. However, the cortex is more than just a way station. It is highly plastic, and distinct cortical areas are reorganized or biased by specific training experiences to meet demands for specific types of perceptual or motor representations.

BEHAVIOR SUPPORTED BY MULTIPLE MEMORY SYSTEMS

The discussion of memory systems so far has focused on dissociations between systems in illustrating the unique contributions of the central structure in each system. However, behavior is a product of the entire nervous system and is typically guided by contributions of more than one form of memory. For example, training in a sport normally results in declarative memory of instructions from one's coach but also leads to motor skill learning from repetitive practice. The memory for the instructions would depend on the hippocampus and various aspects of the skill would depend on the striatum, cerebellum, and motor cortex. The amygdala would likely also contribute during moments of emotional arousal. The following section considers emerging data regarding how the memory systems discussed so far might interact and illustrates some progress in understanding how the distribution of memory throughout the brain ordinarily contributes to our day to day activities.

One example of a direct collaboration between two memory systems is the influence of the amygdala on hippocampus-dependent memory for emotion-inducing material. The section earlier in the chapter on the amygdala discussed how emotional arousal leads to the amygdala engaging in modulation of declarative memory, such that stimuli that elicit either positive or negative emotional responses tend to be remembered better than neutral stimuli. This process is thought to result from amygdalar projections modulating synaptic plasticity either in the hippocampus and parahippocampal region or in cortical areas fundamental to the hippocampal memory system. It has been suggested that the amygdala also modulates other memory systems, such as the striatal memory system, and that the amygdala may play a generalized role in memory modulation for emotion inducing stimuli in addition to its role in attaching positive or negative dispositions to stimuli (McGaugh, 2004).

Another example comes from an indirect collaboration between two very dissimilar memory systems, the hippocampal memory system and the cerebellar memory system. The section earlier in the chapter on the cerebellum detailed that the essential circuitry for standard eyeblink classical conditioning involved no forebrain structures and instead centered on deep cerebellar nuclei. Yet the situation changes if the parameters for standard eyeblink classical conditioning, referred to as delay eyeblink conditioning, are altered slightly such that the tone that normally

overlaps with the airpuff is moved earlier in time such that it terminates as little as a half second prior to the onset of the airpuff, a version called trace conditioning (Christian & Thompson, 2003). Trace eyeblink conditioning depends on the same cerebellar and hindbrain circuitry as delay eyeblink conditioning, but trace conditioning depends additionally on forebrain structures including the hippocampus and prefrontal cortex. In studies with healthy human participants, trace (but not delay) eyeblink conditioning was found to relate closely to participants' knowledge about the relationship between the tone and the airpuff (Clark, Manns, & Squire, 2002). A possible explanation of these findings is that the silent interval that separates the tone and airpuff may surpass the learning abilities of the cerebellum and may cause it to require inputs from additional forebrain structures, such as the hippocampal system via the prefrontal cortex (Kalmbach, Ohyama, Kreider, Riusech, & Mauk, 2009), to bridge that brief interval. The growing understanding of the relationship between hippocampus and cerebellum illustrates the tendency to collaborate between even the most dissimilar memory systems, and exemplifies the progress being made towards understanding how memory systems interact in general.

In other examples, memory systems may not directly collaborate but may operate in parallel. For example, the previously discussed studies contrasting the role of the striatum and hippocampus in supporting "response" learning and "place" learning, respectively, illustrate how the memory supported by different brain systems may not converge. Yet in the example of practicing a sport, the hippocampus-dependent memory for a coach's instructions and the striatal "response" learning would likely support a common behavior. In these instances, it is thought that the striatum and hippocampus contribute to behavior in parallel rather than directly interacting.

CONCLUSION

Several brain systems support distinct forms of memory characterized by unique operating features and ways in which memory is expressed. The hippocampus supports rapidly-acquired memory that is experienced as conscious recollection and that can be expressed flexibly. The striatum supports acquisition of inclinations to make situational responses. The cerebellum supports learning related to adaptive timing and motor reflexes. The amygdala supports acquisition of emotional dispositions towards stimuli and also mediates the role of emotion arousal in modulating other forms of memory. The cerebral cortex participates in each of these types of memory, and mediates perceptual learning, motor learning, and the phenomenon of priming. These systems also often operate in concert to support the various ways that behavior and mental life can be modified by experience.

CHAPTER

49

Language

This chapter discusses the relationship of language to the brain. It begins with a discussion of animal communication, from which human language evolved and that provides a guide to the basic neural elements and processes that underlie our own system of communication. The next section of the chapter provides a brief summary of human language and its relation to the brain, relying on studies of patients with various types of neurological diseases and on brain imaging in normal subjects.

ANIMAL COMMUNICATION

Communication Is Important for Individual Survival

The ultimate goal of most animal communication, like that of behavior in general, is reproduction. Thus, signals that indicate the sender's species, gender, and degree of reproductive readiness account for the vast majority of natural communication. These are the messages being broadcast by chirping crickets, flashing fireflies, pheromone-releasing moths, and singing birds. Frequently, the mate-attraction call is also used to warn off potential rivals; for example, bird and cricket songs are also used to identify the boundaries of territories or personal space. Differences in signal quality are the usual basis of mate choice in species for which some degree of discrimination is evident. This competition for the attention of members of the opposite sex has led to the development of more conspicuous signals and, in many cases, to the evolution of displays, signaling morphology (i.e., sounds vs. shapes vs. color vs. movement vs. odors), and messages that go far beyond the basic needs of species and sexual identification (Gould & Gould, 1996).

Most animals are solitary except when mating; they abandon their eggs or larvae before the offspring are born. However, a number of species engage in some degree of parental care. For them, signals between parent and offspring are often very important. Most birds, for instance, have about two dozen calls that communicate mundane messages such as the need to eat, defecate, take cover, and so on. In cases in which both parents tend the young—the usual circumstance in birds, for instance—additional signals are required to agree on a nest site, synchronize brooding shifts, and guard the nestlings. Most primates also utilize two to three dozen signals for similar purposes.

The minority of species that are highly social have the most elaborate communication systems of all. They need messages for a variety of elements of social coordination, including, in many cases, group hunting or foraging, defense, and working out of a social hierarchy.

Animal Communication Strategies and Mechanisms

To ensure species specificity in mating, most species rely on more than one cue to identify a sexual partner. (Exceptions include some of the species that rely on pheromones.) Thus, multiple signals are sent, and a choice must be made between sending simultaneous messages and sending sequential messages (or a combination of the two). The sequential strategy has the advantage that the individual signals must be correct *and* the order must be appropriate. A female stickleback, for instance, requires the male to have a red ventral stripe, perform a zigzag dance, poke his nose in a nest, and then vibrate her abdomen; the odds of this concatenation of signals occurring together in this order by chance are remote. However, sequential signaling is time-consuming. A faster strategy is to provide all the cues in parallel, an approach that accepts the larger chance that these cues can occur together by chance. For example,

© 2013 Elsevier Inc. All rights reserved.

when a parent herring gull waves its bill in front of chicks to see if they need to be fed, the young simultaneously see a vertical beak, a red spot, and a horizontal motion, each of which is a discrete cue that combine in the mind of the chick to elicit pecking.

Innate and Learned Aspects of Animal Communication

Nearly all animal communication is innate: the sender produces the appropriate signal in the correct context even without any opportunity for learning, and it can be recognized for what it is by equally naive conspecifics. The basis of innate recognition appears to lie with feature detectors in the nervous systems—the inborn circuits that automatically isolate iconic visual or acoustic elements (Gould, 1982). The availability of many visual, auditory, tactile, and olfactory feature detectors, which can, in theory, be used in any specific combination or order, accounts for most of the diversity of animal communication, and reliance on these individual feature detectors, rather than pattern detection, accounts for its limitations. More complex behavior in relatively short-lived species, such as nest building in birds, is also usually innate, although some improvement with experience is also evident (Gould & Gould, 1999, 2007). Therefore, looking at how complex innate communication can be is useful in considering the extent to which as complex a system as human language must be learned.

In terms of its ability to communicate information, the most complex system of nonhuman communication known at present is the dance of honeybees. The system has some properties that are reminiscent of human language: it uses arbitrary conventions to describe objects distant in both space and time; that is, it does not reflect a real-time emotive readout, as might be the case when a primate gives an alarm call or grunts at a banana.

In terms of information content, a honeybee dance is second (albeit a very distant second) only to human speech, and so far as is known is far richer than the language of any primate. However, the dance language suffers from at least two limitations: it is a closed system in that there seems to be no way to introduce new conventions to deal with novel needs, and it is also graded; instead of discrete signals for different directions or distances, single components are varied over a range of values (angles and durations). The less complex but more flexible systems of birds and primates are more likely to illustrate the evolutionary precursors of speech.

Some birds have innate songs. In these species, individuals raised in isolation produce songs that are indistinguishable from their socially reared peers and respond to calls appropriately without prior experience. Chickens, doves, gulls, and ducks are familiar examples. Most songbirds, however, illustrate a different pattern: one that shows how potent a combination instinct and innately directed learning can be. Isolated chicks sing a schematic form of the species song, but the richness of a normal song is absent. Adult conspecifics can recognize innate songs as coming from members of their species, but in general these impoverished vocalizations produce lower levels of response. Typically, there is a sensitive period during which exposure to song must occur if it is going to have any impact (Fig. 49.1). In most species, there is a gap between this sensitive period and the process of overt song development—that is, practice and perfection of the adult song are based on the bird's memory of what it heard during its sensitive period (Gould & Marler, 1987).

Given a range of possible song models during isolated rearing, a chick selects an example from its own species and memorizes it. If it hears only songs of other species, the mature song is the unmodified innate song (Fig. 49.1). Thus there is an innate bias in the initial learning. Where this bias has been studied, it appears to depend on acoustic sign stimuli (i.e., species-specific "syllables"). Chicks are able to extract syllables of their species embedded in foreign songs, or scored in a way never found in their species (e.g., a syllable that is repeated at an accelerating rate presented to a species that sings syllables at a constant rate, or vice versa will be extracted and used in the species-typical manner).

Practice is essential in the normal development of birdsong, and part of this practice occurs in a babbling phase known as subsong, which begins at a species-typical age. A bird deafened after its sensitive period, but before it begins producing notes in preparation for singing (subsong), is unable to produce even an innate song (Fig. 49.1). During the earliest parts of subsong, birds try out a number of notes. These notes are typical of the species, but most are absent from the song they eventually sing. The learning process may involve producing each member of an innate repertoire of notes, listening to them, checking to see if they match any element in the memorized song, discarding the unnecessary ones, and rearranging, scoring, and modifying the others to produce a reasonable copy of the original song heard during the sensitive period.

There is some flexibility in song development. For example, when the chick has heard two very different specimens of its own species' song, it will often incorporate elements from each. Similarly, when the chick has been exposed to the sight of a singing conspecific and simultaneously the sound of a heterospecific song, it may pick out elements of the abnormal song and adapt them as best it can into its own species-specific organization.

Birdsong, therefore, depends on two processes that involve an interaction between innate capacities and learning: imprinting the song in memory and then learning to perform it. This system is flexible, but only within clear limits.

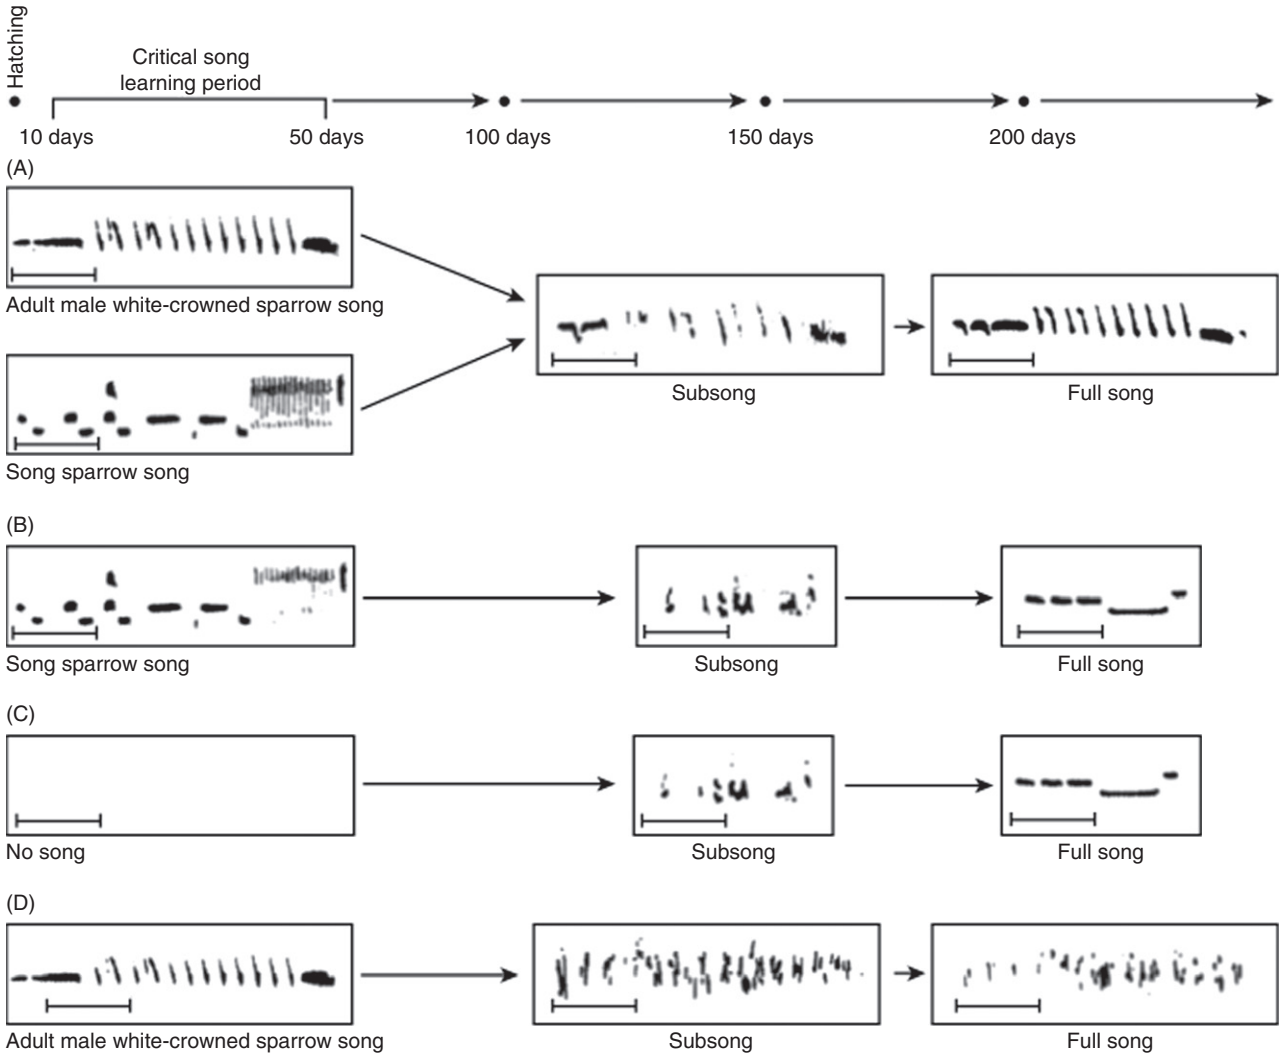

FIGURE 49.1 Birdsong development in most species is characterized by a sensitive period during which a song of the species must be heard. Later, during subsong, the bird practices making notes and assembles them into the correct order and pattern (A). Birds not allowed to hear their species' song sing a schematic version of the song (B and C); birds deafened before subsong cannot sing (D).

Communication Systems in Primates

Primates are the species with the closest evolutionary links to humans, and therefore the communication systems found in these animals are important to study for clues regarding the neural basis of human language.

Vervets, a species of monkey, provide a good case study. Vervets, like all social primates, have a large repertoire of innate calls used for social communication. Among these approximately three dozen signals are four alarm calls (Cheney & Seyfarth, 1990). In some parts of their range, one of the calls is specific for martial eagles; in another, the same call is used for certain hawks. In either case, the call causes monkeys to look up; those at the tops of trees drop to the interior, whereas those on the ground move into bushes or under trees. A second call, specific to leopards in one region and to other solitary hunters elsewhere, sends the warned individuals up to the tree tops. A third, specific for snakes, induces the other members of the troop to stand up and look around in the grass. A fourth call is heard in the presence of humans or group-hunting predators.

The development of calling is revealing. Young vervets appear to understand the class of animals each call refers to, but not the particular species that are dangerous. Thus, infants will give the eagle call to harmless vultures, storks, and even falling leaves, but not to snakes or leopards. Consequently, adults generally respond to the alarm calls of infants with a casual look around, followed by their own alarm if there is a genuine danger. Juveniles make fewer mistakes, and adult errors are confined to calls produced when the potential threat is so far away that human

observers require binoculars to identify the species. In short, young vervets seem to learn the details of how to apply an innate categorical vocabulary.

Nonhuman primates have virtually no voluntary control over respiration, the vocal tract, or vocalization, so this modality is not available for producing a large number of differentiated signals. Other modalities of communication, such as gesture, however, are also used for relatively restricted purposes, mostly related to items of immediate biological importance and social hierarchy. Recent detailed studies of gesture use in captive chimpanzees indicate that the meanings of particular gestures differ from one group to another.

Reseachers have attempted to teach chimpanzees to use a variety of communicative systems that bypass their vocal limitations, such as sign language and manipulation of object tokens, in an effort to determine to what extent these naturally occurring communication systems can be augmented. If anything, this work emphasizes the ways in which nonhuman primates are not capable of full human language. There are dramatic differences between trained chimpanzees and humans in terms of vocabulary size (chimps never get beyond what a 2-year-old can do), conceptual capacities, complex grammar, and so on, despite the fact that chimps have remarkable skills at social cognition.

Neural Structures for Animal Communication Systems

The neural mechanisms that underlie animal communication may give clues as to those that allow for human language. These systems of course differ in different phyla and species. This section briefly reviews aspects of the neural basis for birdsong and primate communication. It would be of great interest to report on the neural basis for the dance of the bees, but nothing is known about this subject.

Birdsong

Birdsong appears to be produced by a small number of nuclei (collections of nerve cells). In the canary, four important nuclei are involved: HVc, RA, DM, and nXIIts. Lesions in any of these nuclei destroy or seriously impair song production. These nuclei also respond when song is presented, and some neurons in some nuclei in some species (e.g., neurons in nXIIts in the zebra finch and the white-crowned sparrow) respond specifically to particular aspects of song. This indicates an overlap in the neural mechanisms involved in song perception and production, a feature that may carry over to humans as well.

Birdsong is produced by a structure between the trachea and the bronchi called the syrinx. There is one syrinx on each side of the trachea. In some species, song is entirely, or mainly, produced by one of these two structures; in other species, both syrinxes participate in song, with each producing different parts of the song. Each syrinx is controlled by structures in its corresponding side of the brain and, when one syrinx is responsible for song, these structures are larger on that side. The perceptual system is also duplicated on both sides of the brain, and, in some species, the two sides of the brain respond to different aspects of song.

In species in which only male birds sing (most species), song nuclei are much larger in males than in females ("sexual dimorphism"). This is not true in those species in which males and females perform duets. In general, there is a correlation between song nucleus size and song complexity in individual birds. Furthermore, song nuclei grow by a factor of almost 100% during the spring mating season (when birds sing) compared to the fall and winter (when they do not).

Changes in the size of song nuclei are related to testosterone production (they can be induced in females by testosterone injection in some circumstances) and by other factors usually related to day length—part of the birds' innate calendar. They are due to many changes in nerve cells: increase in the number of dendrites, increase in cell size, and, most interestingly, increase in the number of cells. Studies using labeled thymidine, which is taken up by dividing DNA, have shown neurogenesis in neurons in the HVc nucleus in relationship to periods of increased song, indicating that new nerve cells are formed. These neurons project to the RA nucleus, strongly suggesting that they play a role in song.

Primates

The neural basis for primate vocalizations is beginning to be charted. Unlike humans, vocalizations in primates do not appear to begin in a lateral cortical region but rather in the medial portion of the brain (the cingulate), a region involved in connecting basic instinctual to more advanced cognitive functions. Actual motor planning appears to involve mainly brainstem nuclei. On the perception side, there are neurons in the auditory cortex of some species of macaque monkeys that selectively respond to conspecific calls. These regions show some degree of functional asymmetry in some species, with responses from cells in the left hemisphere and not the right.

Possible Lessons from Nonhuman Species Regarding Language and Its Neural Basis

It is dangerous to infer too much about human language, or about how the human brain may support language, from studies of species that are very distant, such as birds. However, these species provide evidence for the possibility of certain aspects of language and its neural basis that could have developed several times in evolution or that could date to a distant common ancestor.

At a behavioral level, human speech and language could have developed from the repertoire of two to three dozen innate calls that are typical of birds and primates. In that case, we would expect to find that language contains elements that are innately recognized and that may be distinguished by the sorts of acoustic features that provide the basis for the innate discrimination of sign stimuli in other species. In fact, babies have an innate ability to discriminate a small number of sounds found in human languages, which function as acoustic sign stimuli. The evolution of human speech could also have retained the sorts of sensitive periods and innate learning biases so evident in song birds and vervet monkeys. In this case, we might expect to see a species-typical babbling phase, and perhaps a sensitive period for easy learning of new languages. If the evolution of speech and language preserves the use of preexisting (innate) forms, we might expect there to be innate aspects of human language, which would presumably be found in all languages and which might surface in situations where we see a "default grammar," not unlike the unlearned and impoverished songs of birds reared in isolation. Creoles potentially exemplify such cases. Creoles are languages developed by the children of people speaking different languages who are drawn together and communicate with very simple pidgin. They have a number of features not present in the languages spoken by the parents of the children who spoke the pidgin, which have been taken to be related to innately specified features of language (Bickerton, 1990).

From the neurological perspective, several features of the neural organization for communication systems appear to be found in humans in a way that is relevant to language. These features are the fact that there are specialized neural nuclei for song production; that the neural basis for song production is often asymmetric, with one hemisphere producing most of song or the two hemispheres producing different aspects of song; that production and perception of song use the same structures to some degree; and that there is a relationship of size to function. However, other important features of the neurobiology of birdsong, such as the neurogenesis that is important in the seasonal changes in song production, are not known to play a role in human speech and language. As for primates, the neural system responsible for call production is quite different from that in humans, being based in the cortex that is transitional from limbic to association regions (reflecting the limited semantic content and immediate biological relevance of most calls). Asymmetries in the neural basis for call perception, and the existence of neurons in the auditory association cortex that selectively respond to conspecific calls, may be quite direct evolutionary precursors of the human neural substrate for language.

HUMAN LANGUAGE

Human language differs from animal communication systems in many ways. Functionally, as we have seen, most animal communication systems serve the purposes of identifying members of a species and designating items of immediate biological significance. Human language provides means to designate an infinitely large number of items, actions, and properties of items and actions. Human language also allows items, actions, and properties to be related to one another, and for relationships between events and states of affairs in the world, such as temporal order and causation, to be represented at the level of discourse. Language expresses these different semantic values with different types of representations: words, words made from other words, sentences, and discourse. Each of these "levels" of linguistic representation consists of specific forms that are related to specific aspects of meaning. The forms at each level are intricately structured, and there are an infinite number of different structures that can be built at each level of the system.

Language Processing

Current models of language processing subdivide functions such as reading, speaking, auditory comprehension, and writing into many different, semi-independent components, which are sometimes called "modules" or "processors." These components can be further divided into variable numbers of highly specialized operations, such as those involved in mapping features of the acoustic signal onto phonemes or in constructing syntactic structures from words. Each operation accepts only particular types of representations as input and produces only specific types of representations as output.

Models of language processing are often expressed as flow diagrams (or "functional architectures") that indicate the sequence of operations of the different components that perform a language-related task. Figure 49.2 presents a basic model illustrating the functional architecture of the lexical processing system. Figure 49.2 is greatly simplified because not all components are represented, parallel feedforward and feedback pathways are not depicted, and the nature of the operations in each component is not specified.

Some important operating characteristics of components of the language processing system emerged from experimental studies. These include the following features:

1. Language processors are highly specialized. For instance, recognition of phonemes is accomplished by mechanisms that appear to separate very early in the processing stream from those that recognize other auditory stimuli.
2. Language processors are obligatorily activated when an individual attends to the input. For instance, if we

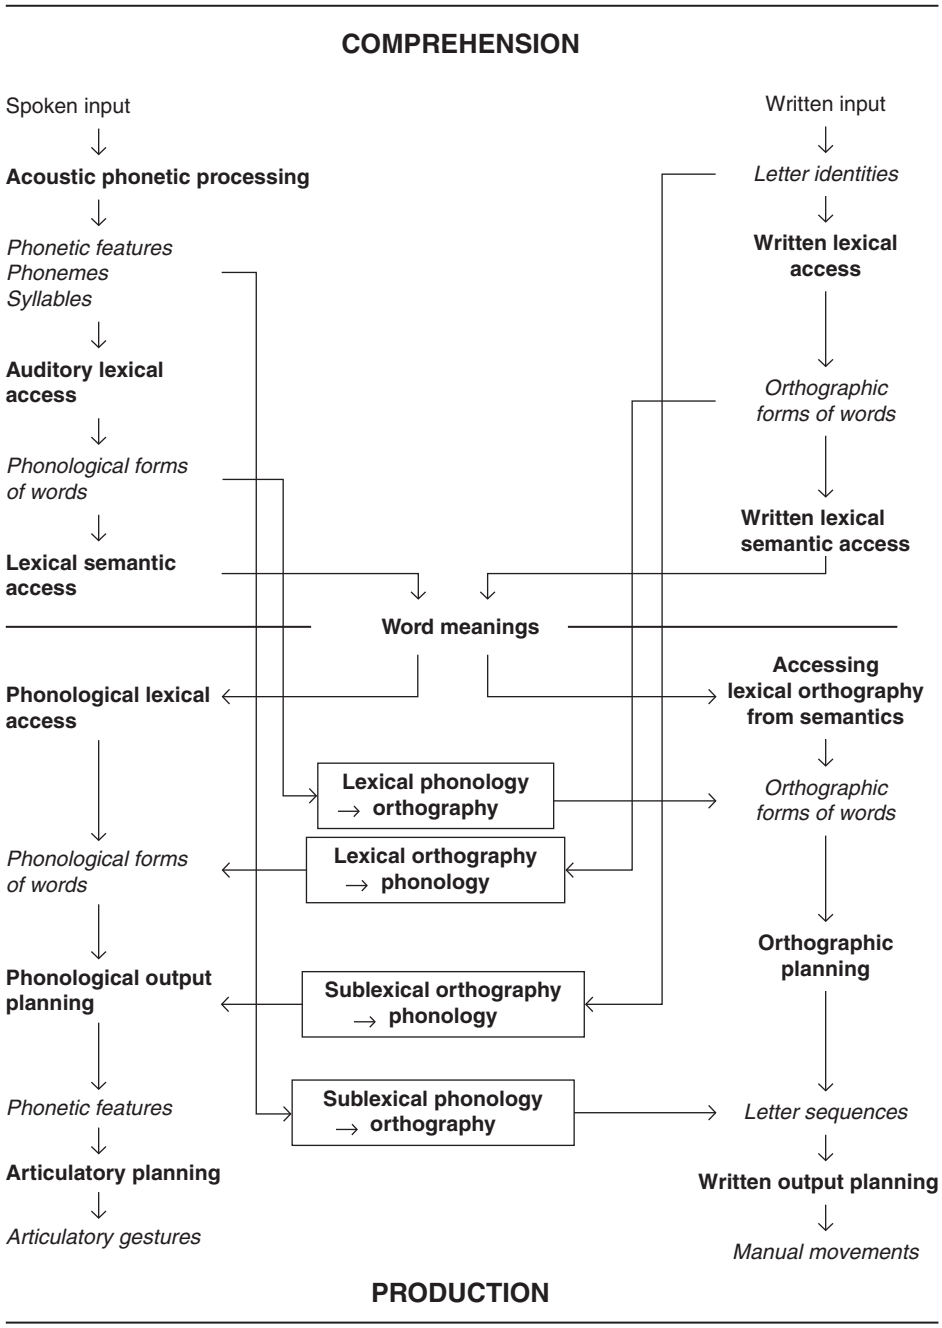

FIGURE 49.2 A model of the major psycholinguistic operations involved in processing simple words.

attend to a sound that happens to be the word "elephant," we must hear and understand that word; we cannot hear this sound as just a noise.

3. Language processors generally operate unconsciously.
4. Language processors operate quickly and accurately. For instance, it has been estimated on the basis of many different psycholinguistic experimental techniques that spoken words are usually recognized less than 125 ms after their onset—that is, while they are still being uttered. The speed of the language processing system as a whole occurs because of the speed of each of its components, but also is achieved because of the massively parallel functional architecture of the system, which leads to many components of the system being simultaneously active.
5. Language processors require "processing resources." Although we do not appreciate it consciously, language processing demands some effort. It is unclear whether there are separate pools of processing resources for each language processing

component or for language processing as a whole or whether language processing can "borrow" resources from other systems if it needs to.

Language develops, without explicit instruction, in the auditory-oral modality, if this channel is available. Prelingual deafness leads to language developing in the visual and gestural modalities. Languages can also be represented orthographically, using a variety of scripts (alphabetic, syllabic, consonantal, ideographic). Many of the features of spoken language processing we have reviewed apply to the processing of written and signed language as well, though there are differences due to constraints imposed by the modality of presentation. For example, written language does not develop in the absence of explicit instruction.

Language Universals, Language Acqusition, and Language Evolution

By some counts, there are over 6500 languages in the world. These languages differ in many ways from one another: they have different vocabularies, use different sounds, and have different ways of forming words and different syntactic rules. However, beyond these surface level differences, there are features that are common to all human language. For instance, the sound systems of all human languages consist of alternations of consonants and vowels; no language forms different words by varying features of sound such as its loudness or whether a word is whispered. These "linguistic universals" form a framework within which the features of individual languages occur.

Linguistic universals can arise because of universal features of motor or sensory systems or, possibly, because of constraints on cognitive computational capacities. They may also arise because language itself is constrained to have certain features. Chomsky's work in the area of syntax is the best known and most controversial example of analyses along these lines (Chomsky, 1965, 1995). Chomsky and his colleagues and students have argued that very abstract features of syntax are common to all languages. There have been numerous suggestions as to what these features are; one recent proposal is that they include the ability to generate an infinite number of expressions from a finite set of elements (Hauser, Chomsky, & Fitch, 2002). Many linguists believe that the structure of language is much less abstract than Chomsky and his colleagues have suggested and, accordingly, that universal "laws" of linguistic structure are also less abstract, mostly taking the form of statements that the presence of one type of element in a language implies that a second type will also be present.

The issues of how abstract linguistic representations are and what universal properties of language exist are bound up with two major issues—how language is acquired and how language evolved—that are in turn relevant to the neural basis for language. Chomsky's view is that language acquisition consists of fixing the parameters in an innate language template that correspond to the constraints on possible forms of human language that are present in the language a child is exposed to. A parallel in nonhuman learning might be imprinting (Immelmann, 1972), whose neurological basis has been studied very little. Models of language that see language structures as much less abstract argue for less elaborate innate knowledge and a greater role for learning in the development of language abilities (e.g., Seidenberg, 1997; Tomasello, 2003).

The same disagreements affect ideas about how language evolved. In Chomsky's model, a critical neural development is the emergence of structures and processes in the brain that support universal properties of language. Assuming recursion is one of these universal properties, the finding that starlings can discriminate a recursive from nonrecursive sequences of notes (Gentner, Fenn, Margoliash, & Nusbaum, 2006) implies that some of these neural structures are not unique to humans, but if recent studies showing that some species of monkeys do not recognize recursive structures are true of all higher primates, the evolutionary path for these features must have taken a number of divergent paths and reemerged in humans. The major alternative to the view that language evolution consisted of the emergence of neural structures capable of supporting abstract organizational features that are found in all human languages is that language rests upon an evolutionary change that supports much less complex and abstract representations and the complexity of human language is a cultural development, like architectural complexity.

One well-known model of this sort that has a neural basis has been developed by Rizzolati and Arbib (1998), who have argued that the neural structures that are critical for language are modifications of the mirror neurons found in monkeys that fire both when the monkey grasps particular objects and when the animal sees a person grasping those objects. In Arbib and Rizzolati's view, these neurons encode the relation of a number of actors to an action and an object, and thus lay the basis for neural mechanisms that allow an arbitrary number of substitutions of actors and objects in relation to the action described by a verb. We note that the fact that culture influences what structures a language has (Everett, 2005) does not resolve this debate, because any neurologically normal human infant would presumably learn the language of his or her environment.

There are very limited empirical data regarding the neural and genetic basis for the evolution of human language. Lieberman (2006) argues that the critical evolutionary change that made for human language was not specifically neural but consisted of the descent of the root of the tongue into the oropharynx, which allows humans

to produce the inventory of speech sounds of a language. In his view, two genetic effects—increases in the size of the hominid brain related to the ASPM gene and, more importantly, changes in the ability to exploit the increased channel capacity in humans by changes in the FOXP2 gene—underlie the use of the resulting increase in the vocal repertoire for communicative purposes. Deficits in the FOXP2 gene in a single family have been associated with a variety of language and articulation problems, and the FOXP2 gene has been referred to as a (or "the") "language gene" by some researchers, However, the deficits in affected family members are not specific to syntax or word formation, and, as Lieberman argues, it is more likely that this gene codes for neuronal features of subcortical gray nuclei, in particular the basal ganglia and, to a lesser extent, the cerebellum that make for more elaborate and efficient control of sequencing abilities than for cortical structures that represent and process language *per se*.

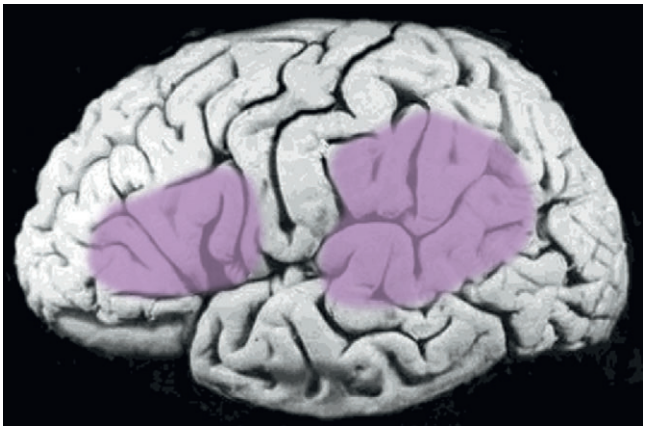

FIGURE 49.3 A depiction of the left hemisphere of the brain showing the main language areas. The area in the inferior frontal lobe is known as Broca's area, and the area in the superior temporal lobe is known as Wernicke's area, named after the nineteenth-century physicians who first described their roles in language. Broca's area is adjacent to the motor cortex and is involved in planning speech gestures. It also serves other language functions, such as assigning syntactic structure. Wernicke's area is adjacent to the primary auditory cortex and is involved in representing and recognizing the sound patterns of words.

NEURAL ORGANIZATION FOR LANGUAGE

An Inventory of Brain Structures Related to Language

Human language depends on the integrity of the unimodal and multimodal association cortex in the lateral portion of both cerebral hemispheres. This cortex surrounds the sylvian fissure and runs from the pars triangularis and opercularis of the inferior frontal gyrus [Brodman's areas (BA) 45, 44: Broca's area] through the angular and supramarginal gyri (BA 39 and 40) into the superior temporal gyrus (BA22: Wernicke's area) (Fig. 49.3). For the most part, the connections of these cortical areas are to one another and to the dorsolateral prefrontal cortex and lateral inferior temporal cortex (Fig. 49.3). These regions have only indirect connections to limbic structures. These areas consist of many different types of association cortex, devoted not to sensation or motor function but to a more abstract type of analysis. The nature of this cortex and its patterns of connectivity are thought to combine to give language its enormous representational power and to allow its use to transcend biological immediacy.

The evidence that language involves these cortical regions was originally derived from deficit-lesion correlations. Patients with lesions in parts of this cortex have been described who have had long-lasting impairments of language ("aphasia"). Disorders affecting language processing after perisylvian lesions have been described in many different types of disease, in all languages that have been studied, in patients of all ages and both sexes, and in both first and subsequent tongues, indicating that this cortical region is involved in language processing independent of these factors. Functional neuroimaging studies have documented increases in regional cerebral blood flow (rCBF) using PET or blood oxygenation level-dependent (BOLD) signal using fMRI in tasks associated with language processing in this region. Event related potentials whose sources are likely to be in this region have been described in relationship to a variety of language processing operations. Stimulation of this cortex by direct application of electrical current during neurosurgical procedures interrupts language processing. These data all converge on the conclusion that language processing is carried out in the perisylvian cortex.

Regions outside the perisylvian association cortex also appear to support language processing. Working outward from the perisylvian region, evidence shows that the modality of language use affects the location of the neural tissue that supports language, with written language involving the cortex closer to the visual areas of the brain and sign language involving brain regions closer to those involved in movements of the hands than movements of the oral cavity. Some ERP components related to processing improbable or ill-formed language are maximal over high parietal and central scalp electrodes, suggesting that these regions may be involved in language processing. Both lesion studies in stroke patients and functional neuroimaging studies suggest that the inferior and anterior temporal lobe is involved in representing the meanings of nouns. Activation studies also implicate the frontal lobe just in front of Broca's area in word meaning. Injury to the supplementary motor cortex along the medial surface of the frontal lobe can lead to speech initiation disturbances; this region may be important in activating the language

processing system, at least in production tasks. Activation studies have shown increased rCBF and BOLD signal in the cingulate gyrus in association with many language tasks. This activation, however, appears to be nonspecific, as it occurs in many other, nonlinguistic, tasks as well. It has been suggested that it is due to increased arousal and deployment of attention associated with more complex tasks.

Subcortical structures may also be involved in language processing. Several studies report aphasic disturbances following strokes in deep gray matter nuclei (the caudate, putamen, and parts of the thalamus). It has been suggested that subcortical structures involved in laying down procedural memories for motor functions, in particular, the basal ganglia, are involved in "rule-based" processing in language, such as regular aspects of word formation, as opposed to the long-term maintenance of information in memory, as occurs with simple words and irregularly formed words. The thalamus may play a role in processing the meanings of words. In general, subcortical lesions cause language impairments when the overlying cortex is abnormal (often the abnormality can be seen only with metabolic scanning techniques), and the degree of language impairment is better correlated with measures of cortical than subcortical hypometabolism. It may be that subcortical structures serve to activate a cortically based language processing system but do not themselves process language. The cerebellum has also increased its rCBF in some activation studies involving both language and other cognitive functions. This may be a result of the role of this part of the brain in processes involved in timing and temporal ordering of events, or in its being directly involved in language and other cognitive functions.

Lateralization

Most language processing goes on in one hemisphere, called the "dominant" hemisphere. Which hemisphere is dominant shows considerable individual differences and bears a systematic relationship to handedness. In about 98% of right-handed individuals, the left hemisphere is dominant. The extent to which left hemisphere lesions cause language disorders is influenced by the degree to which an individual is right handed and by the number of non-right-handers in his or her family. About 60 to 65% of non-right-handed individuals are left hemisphere dominant; about 15 to 20% are right hemisphere dominant; and the remainder appear to use both hemispheres for language processing. The relationship of dominance for language to handedness suggests a common determination of both, probably in large part genetic.

The neural basis for lateralization was first suggested by Geschwind and Levitsky (1968), who discovered that part of the language zone (the planum temporale—a portion of the superior temporal lobe; Fig. 49.4) was larger in the left than in the right hemisphere. Subsequent studies have confirmed this finding and identified specific cytoarchitectonically defined regions in this posterior language area that show this asymmetry. Several other asymmetries that may be related to lateralization have also been identified. The exact relationship between size and function is not known, as there are instances of individuals whose dominant hemisphere is not the one with the larger planum temporale. In general, however, relative size is a good predictor of lateralization. This is another example of the "bigger is better" principle that we saw applied to song nuclei in birds.

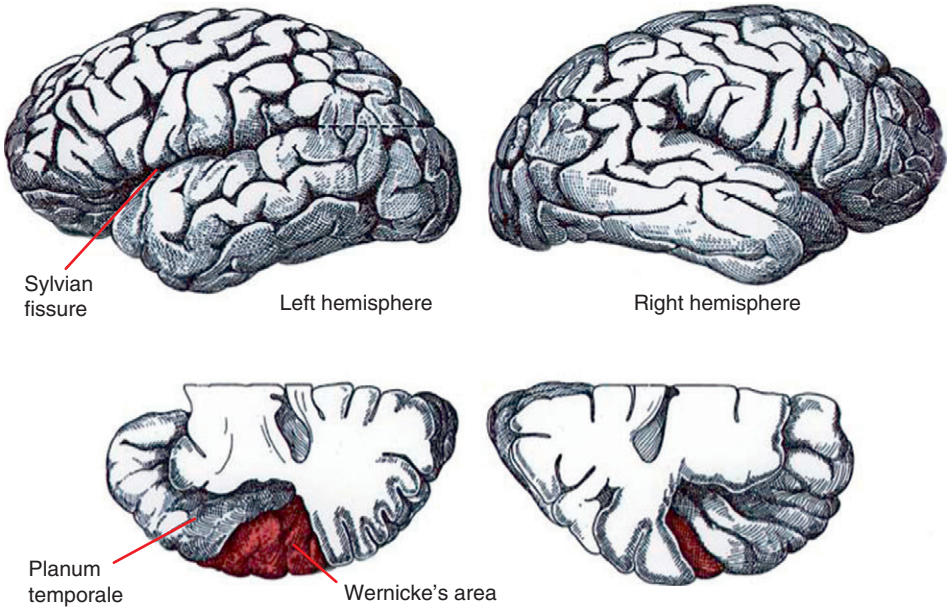

FIGURE 49.4 Depiction of a horizontal slice through the brain showing asymmetry in the size of the planum temporale related to lateralization of language

Although not as important in language functioning as the dominant hemisphere, the nondominant hemisphere is involved in many language operations. Evidence from the effects of lesions and split brain studies, experiments using presentation of stimuli to one or the other hemisphere in normal subjects, and activation studies all indicates that the nondominant hemisphere understands many words, especially concrete nouns, and suggests that it is involved in other aspects of language processing as well. Some language operations may be carried out primarily in the right hemisphere. The best candidates for these operations are ones that pertain to processing the discourse level of language, interpreting nonliteral language such as metaphors, and appreciating the tone of a discourse—for example, the fact that it is humorous. Some scientists have developed models of the sorts of processing that the right hemisphere carries out. For instance, it has been suggested that the right hemisphere codes information in a more general way compared to the left, representing the overall structure of a stimulus as opposed to its details. This may be a general feature of processing in the two hemispheres and apply to other functions, such as visual perception.

Organization of the Perisylvian Cortex for Language Processing

Historically, theories of the relationship of parts of the perisylvian association cortex to components of the language processing system have included distributed ("holist") and localizationist models. Contemporary studies have strongly supported the latter, and we will selectively review representative work.

Evidence for localization of language processing components comes from the finding that selective language deficits occur in patients with perisylvian lesions, often in complementary functional spheres. For instance, some patients have trouble producing the small grammatical function words of language (such as *the, what, is, he*), whereas others have trouble producing common nouns. The existence of these two disorders indicates that the tissue involved in producing function words is not involved in producing common nouns in the first set of patients, and vice versa in the second set.

The first localizationist theories were based on clinical observations in the mid- and late nineteenth century. The pioneers of aphasiology—Paul Broca, Karl Wernicke, John Hughlings Jackson, and other neurologists—described patients with lesions in the left inferior frontal lobe whose speech was hesitant and poorly articulated and other patients with lesions more posteriorly, in the superior temporal lobe, who had disturbances of comprehension and fluent speech with sound and word substitutions. These correlations led to the theory that language comprehension required the unimodal auditory association cortex (Wernicke's area, Brodman area 22) adjacent to the primary auditory cortex (Heschl's gyrus, Brodman areas 41) and that motor speech planning required the unimodal motor association cortex in Broca's area (Brodman areas 44 and 45) adjacent to the primary motor cortex (Brodman area 4). Geschwind (1965) added the hypothesis that word meaning was localized in the inferior parietal lobe (Brodman areas 39 and 40) because word meanings consist of associations between sounds and properties of objects, and the inferior parietal lobe is an area of multimodal association cortex to which fibers from the unimodal association cortex related to audition, vision, and somasthesis project.

This model has many limitations and problems. It only deals with words, not with other levels of the language code. The functions that are localized are entire language tasks, such as comprehension of spoken language or speech production, not components of the language processing system. The correlations between deficits and lesions are found primarily in the chronic stage of recovery from stroke, not in acute or subacute phases of stroke or in other diseases, and even in chronic strokes a very large number of lesions do not occur where the model predicts they will.

Modern studies describe deficits in aphasic patients in terms of specific linguistic representations and psycholinguistic processes. This is similar to modern studies using functional neuroimaging. In the next sections, we review studies of localization of two language processes: spoken word recognition and comprehension, and syntactic operations in comprehension. We have selected these functions because they contrast in several ways; they vary in their abstractness, the extent of the temporal intervals over which they integrate sensory input, and the extent to which current studies converge on localization of the operations they involve. They thus reflect the range of results found in current studies of localization of components of the language processing system.

Lexical Access and Word Meaning

Many of the processes involved in recognizing linguistically relevant units of sound, activating words from these units, and activating the meanings of words appear to rely on specific areas of the brain. This is not evident in the aphasia literature, which shows that both individuals with lesions involving the inferior frontal gyrus (IFG) and those with lesions involving the superior temporal gyrus (STG) display deficits in perceiving acoustic-phonetic stimuli linguistic categories such as phonemes (Blumstein, Cooper, Zurif, & Caramazza, 1977; Blumstein, Tartter, Nigro, & Statlender, 1984). However, results from functional neuroimaging studies with normal participants have provided evidence that speech perception recruits a neural processing stream involving both left posterior

and anterior brain structures (Binder & Price, 2001; Hickok & Poeppel, 2007; Scott & Wise, 2004) and that this neural stream comprises different processing stages that are located in specific areas.

The evidence suggests that temporo-spectral acoustic cues to feature identity are integrated in unimodal auditory association cortex lying along the superior temporal sulcus immediately adjacent to the primary auditory koniocortex (Binder, 2000). Some researchers have suggested that the unconscious, automatic activation of features and phonemes as a stage in word recognition under normal conditions occurs bilaterally. In their view, the dominant hemisphere supports controlled and conscious phonemic processing such as subvocal rehearsal, making explicit decisions in phoneme discrimination and identification and rhyme judgment tasks, and other similar functions.

Based on functional neuroimaging results, activation of the long-term representations of the sound patterns of words is thought to occur in the left superior temporal gyrus. Scott and her colleagues have argued that there is a pathway along this gyrus and the corresponding left superior temporal sulcus such that word recognition occurs in a region anterior and inferior to primary auditory cortex, and that word meanings are activated further along this pathway in anterior inferior temporal lobe bilaterally (Scott & Johnsrude, 2003; Scott & Wise, 2004). This pathway constitutes the auditory counterpart to the visual "what" pathway in the inferior occipital-temporal lobe.

Speech perception is connected to speech production, especially during language acquisition when imitation is crucial for the development of the child's sound inventory and lexicon. On the basis of lesions in patients with Reproduction Conduction aphasia, the neural substrate for this connection has been thought to consist of the arcuate fibers of the inferior longitudinal fasciculus, which connect auditory association cortex (Wernicke's area in the posterior part of the superior temporal gyrus) to motor association cortex (Broca's area in the posterior part of the inferior frontal gyrus). Recent functional neuroimaging studies and neural models have partially confirmed these ideas, providing evidence that integrated perceptual-motor processing of speech sounds and words makes use of a "dorsal" pathway separate from that involved in word recognition.

Hickok and Poeppel (2007) developed the first comprehensive statement of the two-pathway model (Fig. 49.5). They proposed that the ventral stream consists of an acoustic-phonetic conversion process located in STG bilaterally and a "lexico-semantic interface" in the posterior part of the left middle temporal gyrus, which is connected to inferior frontal gyrus. The ventral pathway (to middle temporal gyrus) is activated automatically and unconsciously in the process of ordinary spoken word comprehension. The dorsal pathway transmits phonetic representations from superior temporal gyrus to a left dominant temporo-parietal sensorimotor interface area (Area Spt) that interacts reciprocally with an articulatory network comprising the posterior inferior frontal gyrus, premotor area, and anterior insula. The dorsal pathway is activated in tasks that involve conscious and/or controlled meta-phonological processing and/or (possibly subvocal) rehearsal, such as phoneme discrimination, rhyme judgment, and tasks that involve verbal working memory.

As described above, traditional neurological models maintained that the meanings of words consist of sets of neural correlates of the physical properties that are associated with a heard word, all converging in the inferior parietal lobe. It is now known that most lesions in the inferior parietal lobe do not affect word meaning and functional neuroimaging studies designed to require word meaning do not tend to activate this region. Evidence is accruing that the associations of words include "retroactivation" of neural patterns back to unimodal motor and sensory association cortex (Damasio, 1989), and that different types of words activate different cortical regions. Verbs are more likely to activate frontal cortex, and nouns temporal cortex, possibly because verbs refer to actions and nouns refer to static items. More fine-grained relations between words and activation of sensory-motor brain areas have been described (Pulvermuller, 2005). Hauk, Johnsrude, and Pulvermüller (2004) found activation in primary motor and premotor cortex at the homuncular level of the leg when subjects recognize the written word "kick," the mouth when they recognize "lick," and the hand when they recognize "pick" (Fig. 49.6).

Both deficits and functional activation studies have suggested that there are unique neural loci for the representation of object categories such as tools (frontal association cortex and middle temporal lobe), animals and foods (inferior temporal lobe and superior temporal sulcus), and faces (fusiform gyrus) (see Caramazza and Mahon (2006) for review), and some of these localizations are adjacent to areas of the brain that support perception of features that are related to these categories (animals activate an area of lateral temporal adjacent to the area sensitive to biological motion). Debate continues about how these category effects arise, and whether these activations should be taken as reflecting the meanings of these words. At the same time as these specializations receive support, evidence from patients with semantic dementia and from functional neuroimaging indicates that another critical part of the semantic network that represents word meanings and concepts is located in the anterior inferior temporal lobes. It has been suggested that this region is a "convergence" area, where different properties of items are bound.

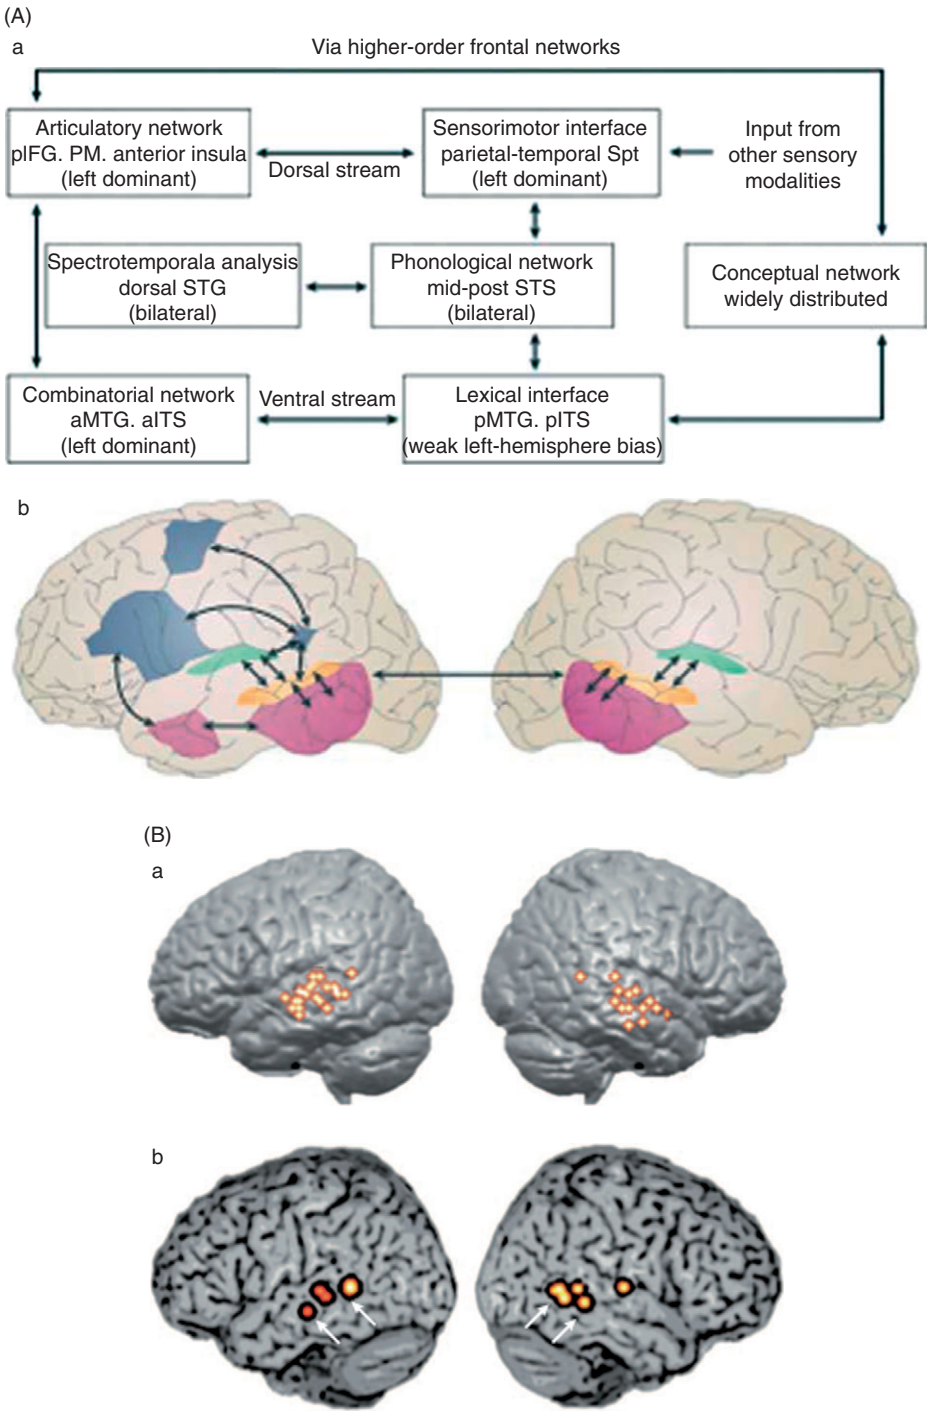

FIGURE 49.5 **(A)** Depiction of the lateral surface of the brain showing areas involved in the functional neuroanatomy of phonemic processing. H is Heschl's gyrus, the primary auditory cortex. STP is the superior temporal plane, divided into posterior and anterior areas. STG is the superior temporal gyrus. Traditional theories maintain that pSTP and STG are the loci of phonemic processing. Hickok and Poeppel (2000) argue that these areas in both hemispheres are involved in automatic phonemic processing in the process of word recognition. Other research suggests that more anterior structures, aSTP and the area around the superior temporal sulcus (STS), are involved in these processes. The inferior parietal lobe (AG, angular gyrus; SMG, supramarginal gyrus) and Broca's area (areas 44 and 45) are involved in conscious controlled phonological processes such as rehearsal and storage in short-term memory (from Hickok and Poeppel (2007)). **(B)** Activation of left superior temporal sulcus by the contrast between discrimination of phonemes and discrimination of matched nonlinguistic sounds (from Hickok and Poeppel (2007)).

Syntactic Operations

We mentioned above that one feature of language is that it allows words to be related to one another to express relations among items and actions and their properties. This "propositional" information is crucial to many human functions, including conveying information stored in semantic memory, planning activities, and others. Languages have "syntactic rules" that determine how words are related to one another. The existence of such rules allows language to express any relation among words, including unlikely or impossible relations, and therefore allows language to express hypothetical events and situations, which is critical to reasoning. Thus, though syntax is not a feature of language that is as familiar to people as words, it is a critical aspect of language. The neural basis of syntactically-based comprehension has been studied

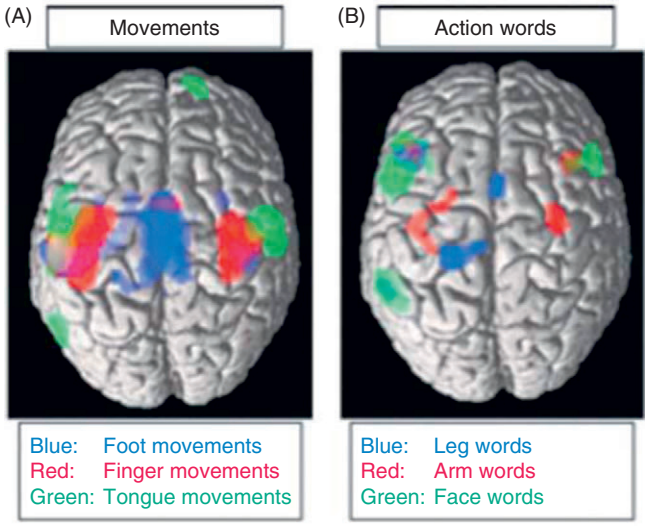

FIGURE 49.6 Activation of areas of the motor strip and premotor area by actions and action words (from Hauk et al. (2004)).

with both deficit-lesion correlations and functional neuroimaging.

Deficits of the ability to use syntax to understand sentences are typically established by showing that patients can understand sentences with simple syntactic structures (e.g., *The boy chased the girl*) and sentences with complex syntactic structures in which the relationships between nouns and verbs can be inferred from a knowledge of real-world events (e.g., *The apple the boy ate was red*), but not sentences with complex structures in which the relationships between nouns and verbs depend on a syntactic structure that needs to be constructed (e.g., *The boy the girl pushed was tall*). Patients with this pattern of comprehension disturbances were first described by Caramazza and Zurif (1976). Among the affected patients were ones with "Broca's aphasia," who produced "agrammatic" speech (speech that lacks function words and morphological markers). Caramazza and Zurif noted that the deficits in comprehension and expressive language of these patients both involved problems with function words, morphology, and syntax, and suggested that these deficits were connected. Their view was that the underlying deficit in these patients affected syntactic "algorithms," and suggested that these rules were supported by Broca's area (the left posterior inferior frontal gyrus), in which lesions were associated with expressive agrammatism. Variants of this hypothesis have been developed by a number of researchers, in particular Grodzinsky (2000), who linked lesions in this area to the loss of quite specific syntactic elements ("traces," in Chomsky's model of syntactic structure).

However, the data that are available indicate that deficits in syntactic processing in sentence comprehension occur in all aphasic syndromes and after lesions throughout the perisylvian cortex (Caplan, Baker, & Dehaut, 1985; Caplan, Hildebrandt, & Makris, 1996; Caramazza, Capitani, Rey, & Berndt, 2001). Conversely, patients of all types and with all lesion locations have been described with normal syntactic comprehension (Caplan et al., 1985). Caplan et al. (2007) studied 42 patients with aphasia secondary to left hemisphere strokes and 25 control subjects for the ability to assign and interpret three syntactic structures in enactment, sentence-picture matching, and grammaticality judgment tasks. In regression analyses, lesion measures in both perisylvian and nonperisylvian regions of interest predicted performance after factors such as age, time since stroke, and total lesion volume had been entered into the equations. Patients who performed at similar levels behaviorally had lesions of very different sizes, and patients with equivalent lesion sizes varied greatly in their level of performance.

Functional neuroimaging studies have also led several researchers to suggest that syntactic processing is localized in Broca's area or in portions of this region (Grodzinsky & Freiderici, 2006). However, most neuroimaging studies show that multiple cortical areas are activated in tasks that involve syntactic processing (Fig. 49.7) and, as with deficit-lesion correlation studies, different studies have shown different patterns of activation.

The discrepancies across studies using both patient data and activation techniques need to be understood. One possibility is that the neural tissue that is responsible for the operations underlying sentence comprehension and syntactic processing is localized in several neural regions, and that the extent to which an area is involved differs in different individuals. This would be consistent with the pattern of deficit-lesion correlations reported by Caplan et al. (2007) but is hard to reconcile with the neuroimaging results because, if it were true, one would expect there to be a variety of activation patterns in the individuals tested in any one study, most likely resulting in no specific activation in most studies. Another possibility is that different studies have involved different aspects of syntactic processing. This could be true of both patient and activation studies.

Pursuing this possibility, we note that poor performance in an aphasic patient can reflect many different deficits. For instance, chance level performance on a sentence type may result from a failure to assign the structure and meaning of a sentence, as many researchers have assumed, but could also result from an intermittent failure to assign structure and meaning. Recent studies using measures of on-line processing (self-paced word-by-word listening, and eye tracking) have provided evidence for the latter: some patients whose performance is at chance have normal on-line processing measures for sentences they interpret correctly and abnormal measures for sentences that they respond to erroneously. Examination of on-line performance in sentences that produced errors

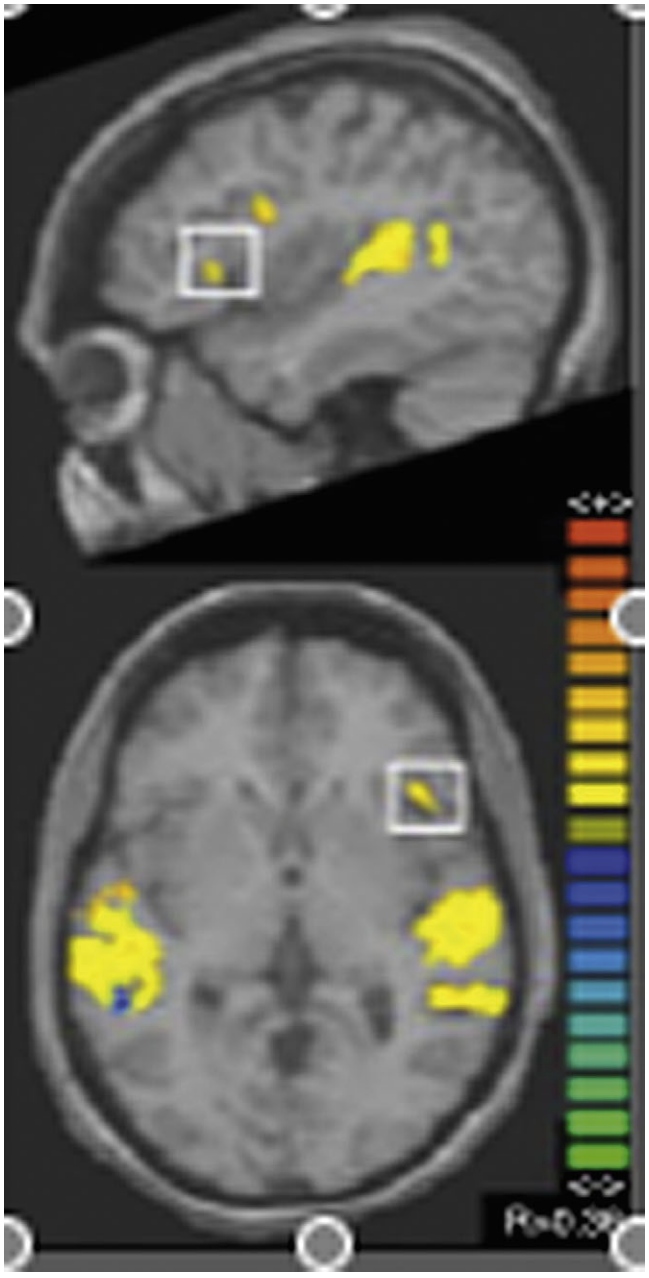

FIGURE 49.7 Activation of Broca's area and superior temporal sulcus when subjects processed sentences with particular syntactic features (questioned noun phrases) compared to matched sentences without those features *From Ben-Shachar, Palti, and Grodzinsky (2004).*

has suggested that a variety of deficits can cause comprehension failure. Some patients show abnormal on-line measures at points of greatest complexity (Caplan et al., 2007), suggesting intermittent overload of resource availability, and others have shown abnormal returns to previously relevant portions of a sentence after the point of maximum processing load has passed, suggesting that the level of a persisting competing interpretation was abnormally high. We have also found that syntactic comprehension deficits most often affect certain structures in only one task: for instance, a patient may be unable to match a sentence to one of two pictures but able to demonstrate its meaning by manipulating objects, suggesting that some deficits arise in the interaction of comprehension with satisfying the demands of different tasks. Different patterns of deficit-lesion correlation in different studies are consistent with localization of the processes that are affected in these different patients in different brain regions.

The variety of activation patterns seen in functional neuroimaging may have a similar explanation. Different sentence contrasts in different studies highlight different syntactic operations and may activate correspondingly different brain areas. In addition, activation related to performing a task, such as encoding sentence meaning in short term memory to answer a question, may also contribute to the results of many studies (Caplan, 2010), though much remains to be learned about the effects of these processes.

CONCLUSIONS

Human language is a unique representational system that relates aspects of meaning to many types of forms, each with its own complex structure. Animal communication systems are neither as complex nor as powerful as human language. Nonetheless, they have some similarities to language and provide clues as to the neural basis of human language. Some language traits are part of a shared evolutionary ancestry with other species, others represent convergent, independent evolution of analogous processes, while yet others must be unique to our species. Perhaps the most important lessons learned from animal studies are that complex communication systems can be innate, that learning can shape an innately specified range of behavioral possibilities, and that communication systems can rely on specific nuclei within the brain and be lateralized. Other features of the neural basis for animal communication systems, such as seasonal variation in the size of birdsong nuclei and the mechanisms that underlie this phenomenon, are not obviously relevant to human language.

Deficit-lesion correlations and neuroimaging studies are beginning to provide data about the neural structures involved in human language. It appears that one general area of the brain—the left perisylvian association cortex—is especially important in representing and processing language (although other regions are involved as well), and that, within this area, many language operations are localized in specific regions. Charting the exact areas that support language operations will require attention to both the nature of the language units that are activated (e.g., different types of sounds, different syntactic structures) and

the tasks that are being performed (e.g., unconscious automatic vs. controlled, conscious phoneme processing; encoding sentence meanings into memory vs. determining if a sentence is plausible). Many possibilities exist, such as that some language functions are localized in very specific regions and others are supported by more widely distributed areas of cortex or by multiple areas of cortex. The way the brain is organized to support different aspects of language still presents exciting challenges and opportunities for discovery for cognitive neuroscientists.

The Prefrontal Cortex and Executive Brain Functions

INTRODUCTION

What controls your thoughts? How do you decide what to pay attention to? How do you act appropriately while dining in a restaurant or listening to a lecture? How do you manage to pursue long-term goals, like obtaining a college degree, in the face of the many distractions that can knock you "off task"? In short, how does the brain manage to orchestrate the activity of millions of neurons to produce behavior that is willful, coordinated, and extends over time? This is called cognitive control, the ability of our thoughts and actions to rise above mere reactions to the immediate environment and be proactive: to anticipate possible futures and coordinate and direct thought and action to them. It is a hallmark of intelligent behavior.

Because cognitive control necessarily involves the coordination of many different brain processes, it no doubt depends on circuits that extend over much of the cerebral cortex. However, one cortical region, the prefrontal cortex (PFC), seems to play a central role. It is the cortical area that reaches the greatest relative size in the human brain and is thus thought to be the neural instantiation of the mental qualities that we think of as "intelligent." Accordingly, the PFC receives converging information from many brain systems processing external and internal information, and it is interconnected with motor system structures needed for voluntary action. Here, we discuss anatomical, neuropsychological, and neurophysiological evidence for, and theories of, the role of the PFC in cognitive control.

ANATOMY AND ORGANIZATION OF THE PREFRONTAL CORTEX

The PFC consists of a collection of cortical areas that differ from one another on the basis of size, density, and distribution of their neurons. Its location in the human brain and major divisions in the monkey brain are shown in Figure 50.1, but these can be further subdivided into at least 18 distinct areas. The PFC is well positioned for a central role in cognitive control. Collectively, these areas have interconnections with brain areas processing external information (with all sensory systems and with cortical and subcortical motor system structures), as well as internal information (limbic and midbrain structures involved in affect, memory, and reward). The subdivisions have partly unique, but overlapping, patterns of connections with the rest of the brain, which suggests some regional differences in function (Fig. 50.2). As in much of the neocortex, however, there are local connections between different PFC areas that can result in an intermixing and synthesis of disparate information needed for cognitive control. Indeed, the PFC has long been suggested to be the great integrator, a brain region that synthesizes information about the external and internal world for the purpose of producing goal-directed behavior.

The PFC is Connected with Sensory Systems

The dorsolateral and ventrolateral portions of the PFC receive visual, auditory, and somatosensory information from the occipital, temporal, and parietal cortices, while

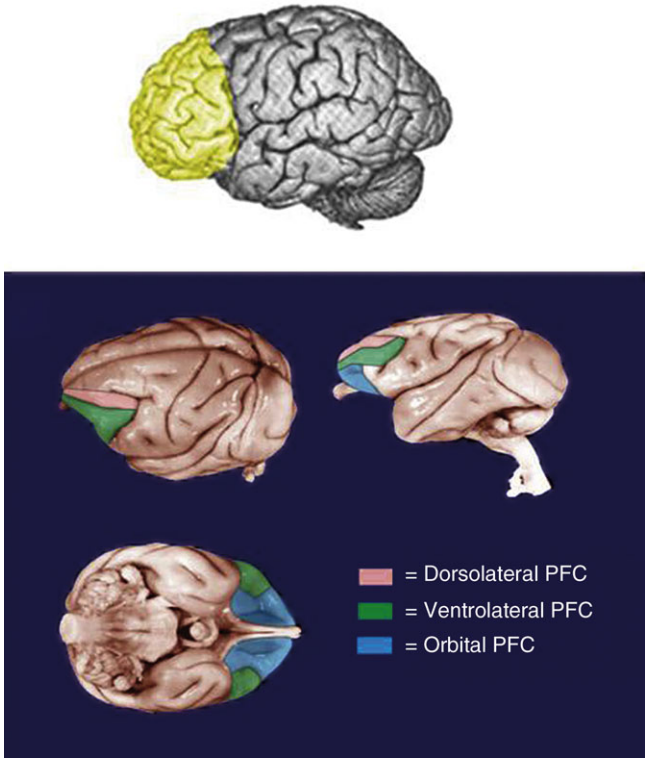

FIGURE 50.1 Location of the prefrontal cortex in the human brain (top) and its major subdivisions in the macaque monkey brain (bottom).

the orbitofrontal cortex receives chemosensory and visceral information (Fig. 50.2). Many PFC areas receive converging inputs from at least two sensory modalities. For example, the dorsolateral (areas 8, 9, and 46) and ventrolateral (12 and 45) areas both receive projections from visual, auditory, and somatosensory cortex. Further, the PFC is interconnected with other cortical regions that are themselves sites of multimodal convergence. Many PFC areas (9, 12, 46, and 45) receive inputs from the rostral superior temporal sulcus, which has neurons with bimodal or trimodal (visual, auditory, and somatosensory) responses to external stimulation. The arcuate sulcus region (areas 8 and 45) and area 12 seem to be particularly multimodal. They contain zones that receive overlapping inputs from all three sensory modalities. In all of these cases, the PFC is not directly connected with primary sensory areas, but instead interconnected with secondary or "association" sensory cortex.

The PFC is Connected with Motor System Structures

The dorsal PFC, particularly dorsolateral area 46, has preferential connections with many motor system structures and may be the primary region by which the PFC exerts control over behavior. Dorsolateral area 46 is interconnected with motor areas in the medial frontal lobe such as the supplementary motor area (SMA), pre-SMA, and the rostral cingulate, with the premotor cortex on the lateral frontal lobe, and with cerebellum and superior colliculus. Dorsolateral area 46 also sends projections to area 8, which contains the frontal eye fields, a region important for voluntary shifts of gaze. As with sensory cortex, there are no direct connections between the PFC and primary motor cortex; the PFC is instead connected with premotor areas that, in turn, send projections to primary motor cortex and the spinal cord. Also important are the dense interconnections between the PFC and basal ganglia (see following).

The PFC is Connected with the Basal Ganglia

The basal ganglia (BG) are a set of subcortical structures that are closely associated with both the motor system and the PFC. The anatomy of the BG is similar to that of the PFC in that they receive converging inputs from virtually every cortical system and many subcortical structures. The region of the BG that receives inputs, the striatum (which includes the caudate and putamen), receives a heavy projection from the PFC. Information then travels through loops of subcortical nuclei, which project back to the frontal cortex via the thalamus. While the PFC projects back to the same wide range of cortical areas that give input to the basal ganglia, the basal ganglia project largely to the frontal lobe motor system structures and the PFC. Thus, the BG are well positioned to influence a wide range of brain functions, albeit with an emphasis on motor output. The anatomical "loops" between the PFC and BG have inspired theories of their close interdependency. This will be discussed following. Basal ganglia anatomy and functions are discussed in greater detail in Chapter 30.

The PFC is Connected with the Limbic System

The orbital PFC is more closely associated with medial temporal limbic structures critical for long-term memory and "internal" information, such as affect and motivation, than other PFC regions. It has direct and indirect (via the thalamus) connections with the hippocampus and associated neocortex, the amygdala and hypothalamus. It has strong connections with olfactory and gustatory cortices, but weaker connections than the lateral PFC to parietal and temporal cortices.

Intrinsic PFC Connections May Provide a Substrate for Diverse Information to Interact

Like most of the neocortex, many PF connections are local. There are not only interconnections between the major subdivisions, but also interconnections between their constituent areas. The lateral PFC is particularly well

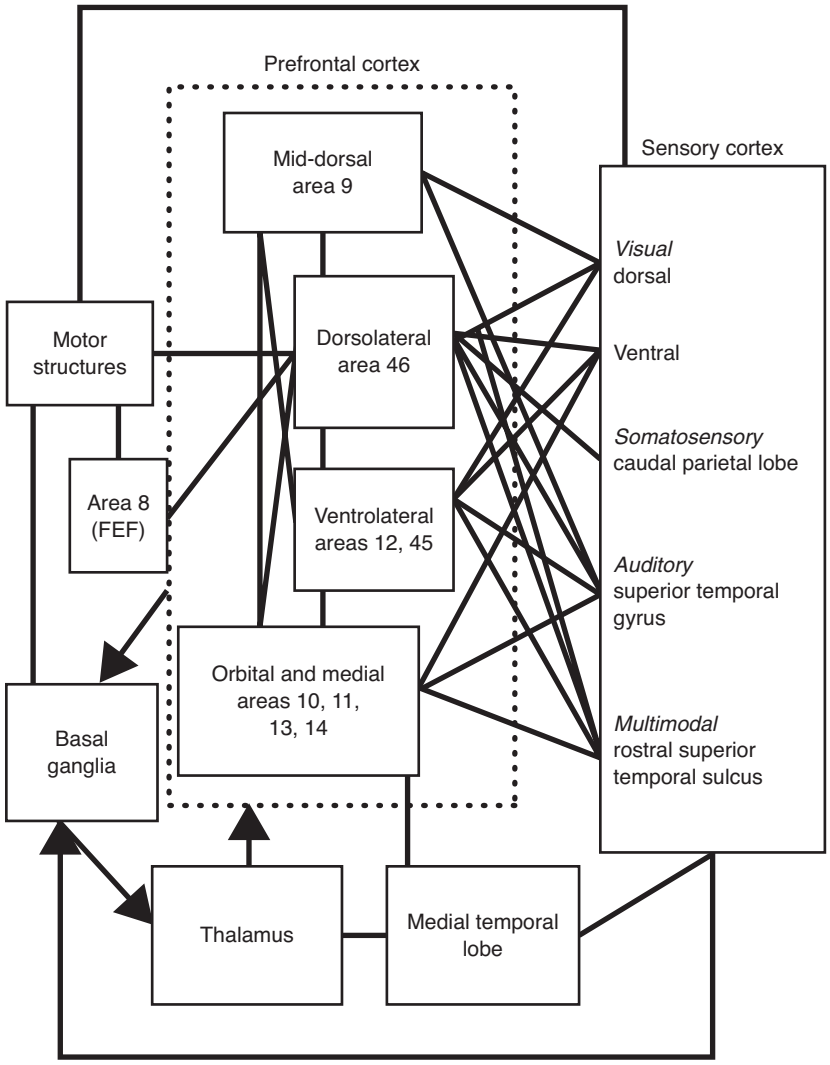

FIGURE 50.2 Schematic diagram of some of the extrinsic and intrinsic connections of the PFC. Most connections are reciprocal; the exceptions are noted by arrows. *From Miller and Cohen (2001).*

connected. Ventrolateral areas 12 and 45 are interconnected with dorsolateral areas 46 and 8, with dorsal area 9, and with orbitofrontal areas 11 and 13. Intrinsic PFC connections presumably allow information from a given PFC afferent or from a given process within a PFC subregion to be distributed to other parts of the PFC.

Summary

The PFC is anatomically well situated to play a role in cognitive control. It receives information from and sends projections to forebrain systems that process information about the external world, motor system structures that produce voluntary movement, systems that consolidate long-term memories, and systems that process information about affect and motivational state. This anatomy has long suggested that the PFC may be important for synthesizing external and internal information needed to produce complex behavior.

EFFECTS OF DAMAGE TO THE PREFRONTAL CORTEX IN HUMANS

PFC Damage in Humans Results in a "Dysexecutive Syndrome"

The PFC occupies a far greater proportion of the human cerebral cortex than in other animals, suggesting that it might contribute to those elusive cognitive capacities that separate humans from animals. However, unlike electrical stimulation of more posterior regions that produce hallucinations or motoric responses, stimulation of the PFC produces no obvious effect. This led it to be termed "silent cortex." Similarly, at first glance, PFC damage has remarkably little overt effect; patients can perceive and move, there is little impairment in their memory, and they can appear remarkably normal in casual conversation. The most infamous case is that of Phineas Gage, a railway construction foreman. In 1848, he suffered an accident in

which an iron bar exploded and was projected up through his chin and out of the top of his head, destroying much of his medial PFC in the process (Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994) (Fig. 50.3). He survived, but it soon became clear that Gage had changed. While he had once been an efficient foreman, he was now irreverent and profane, rude to his coworkers, and unable to organize and plan the work that needed carrying out.

Despite the superficial appearance of normality, PFC damage seems to devastate a person's life. Take the case of Elliot, a successful, happily married accountant, and by all accounts a responsible person. In his late thirties, he was diagnosed as having a prefrontal meningioma, and during the removal of the tumor, his PFC was damaged. Within a few years of the operation, Elliot had divorced his wife, got married and divorced again, lost touch with his family and friends, acquired a disreputable business partner, and lost his business. All of Elliot's basic mental functions seemed to be intact, his language and memory abilities seemed normal, and on tests of intelligence he consistently performed in the superior range.

FIGURE 50.3 Reconstruction of damage to Phineas Gage's brain. *From Damasio et al. (1994).*

What Elliot seemed to lack was the ability to coordinate his mental functions in a manner that took long-term concerns (unseen goals) into account. He became impulsive, lurching from one catastrophe to another based on his momentary whims.

Note that this scenario is exactly what would be expected from the loss of a cognitive control system. Damage to the higher-order, executive functions leaves the components of complex behavior intact and able to be elicited by the appropriate external trigger. But the individual would not be able to coordinate these behaviors with respect to goals and task-specific constraints. For example, there was a PFC patient who, when preparing coffee, first stirred and then added cream. Because of this apparent dysfunction in the top-down control over behavior, the pattern of deficits following frontal lobe damage has been thought to reflect a lack of goal-directedness and the result is called the dysexecutive syndrome.

Humans with Frontal Damage Are Disinhibited

One of the most striking features of prefrontal patients is their disinhibition and lack of behavioral control. The patients are often impulsive, quick to anger, and prone to making rude and childish remarks. For example, one patient complained of being "much more outspoken" since her injury, while another stated, "I've become impulsive since the accident. If I have something to say, I can't wait and have to say it straight away."

An example of disinhibition is utilization behavior. During a medical examination, a patient with PFC damage will pick up and use items that have been left on the doctor's desk. For example, the doctor might leave a comb on the desk, and the patient will pick up the comb and start combing his hair. In one extreme case, a patient used a urinal that the doctor had left on the desk! More formal tests of disinhibition include the Stroop test (Fig. 50.4A). It requires the patient to name the color of the ink in which a word is written. The catch is that the word is the name of another color. Patients have difficulty inhibiting the saying of the word itself because the word elicits a strong, prepotent tendency to read it.

Such tests require patients to inhibit previously established specific responses, but PFC patients are also impaired at inhibiting more abstract behavioral demands like rules. Consider the Wisconsin Card Sorting Test (WCST) (Fig. 50.4B). The patient is required to sort a deck of cards on which are printed a number of symbols. The cards differ from one another in the color and shape of the symbols and the number of symbols per card. The patient's task is to sort the cards according to a given criterion—for example, "Sort by shape." At this point the patients perform the task as well as control subjects. However, when the criterion is changed—for example, to "Sort by number"—the patients are impaired; they are unable to

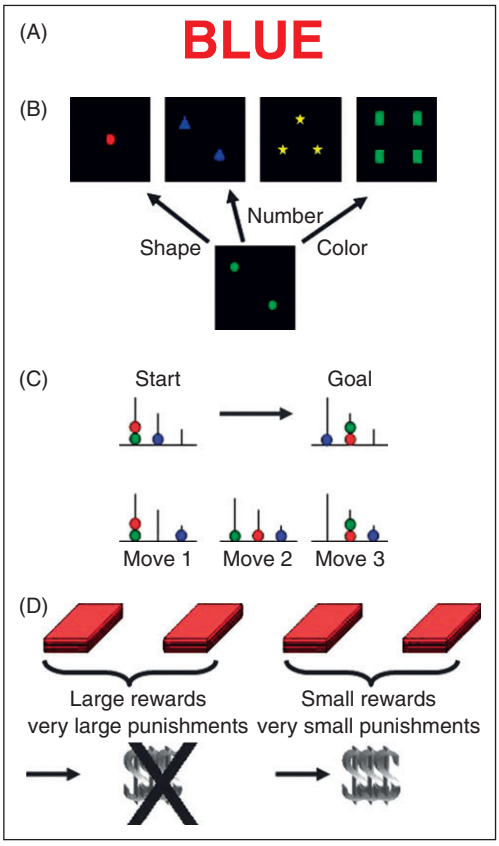

FIGURE 50.4 Tasks used to assess PFC dysfunction in humans. (A) Stroop task. (B) Wisconsin Card Sort. (C) Tower of London task. (D) Gambling task. See text for explanation of tasks.

inhibit sorting by the previous rule. This behavior that is continuing to perform a previously reinforced behavior even though it is no longer rewarded is called perseveration and is characteristic of a prefrontal patient's performance on a wide variety of tasks.

This inability to ignore irrelevant stimuli and the actions they trigger has led PFC patients to be described as stimulus-bound, and the disruption of the patient's ability to think and plan has been termed *goal neglect* (Duncan, Emslie, Williams, Johnson, & Freer, 1996). Without the influence of the goal-related signals from the executive functions, the systems always respond reflexively to an input with whatever output is strongly connected to it.

Humans with Frontal Lobe Damage Have Emotional Impairments

PFC damage produces a marked alteration of a patient's moods and emotions. In the case of Phineas Gage, these changes were so profound that his friends commented, "Gage is no longer Gage." Patients typically display an emotional shallowness, being indifferent and apathetic both to their own situation and to the needs of others. For example, one patient stated, "If I saw someone cry, I'd just laugh; people look silly getting upset." Formal tests show that patients are less able to recognize the emotional expressions of others, though their ability to identify faces remains intact. Patients also become more irritable, aggressive, and prone to angry outbursts. Their humor, termed *Witzelsucht*, becomes compulsive, puerile, and facetious. The patients are aware of these changes even if they are indifferent to them. For example, one patient commented, "Emotion, tears, that's all gone out of the window," while another stated, "I'm much more aggressive, and I feel much less fear. I go fighting for no reason; I don't get anxious."

Humans with Frontal Damage Have Difficulty in Planning and Decision Making

Prefrontal patients have a great deal of difficulty planning and organizing their lives. Wilder Penfield, a neurosurgeon during the mid-twentieth century, described the case of his sister, whom he operated on to remove a large frontal tumor. Prior to the surgery she had been an excellent cook, and while her basic culinary skills remained subsequent to the operation, she seemed unable to organize her behavior so that all the elements of the meal were ready simultaneously. Instead she would move haphazardly from preparing one part of the meal to another, so that some parts of the meal would be burned, while others had hardly been started.

Formal tests have been developed to measure the ability of patients to organize their behavior. For example, the Tower of London Test requires the patient to think several moves in advance (Fig. 50.4C). There are three vertical posts that have three colored rings that can be placed on the posts. The three posts are of different lengths such that the first post can accommodate all three rings, the second post can accommodate only two, and the third post just one. From an initial starting position the patient is asked to move the rings one at a time, from one post to another, to attain a specified goal position. This task requires the patient to plan a number of subgoal positions in order to reach the final goal. Patients with prefrontal damage are greatly impaired at this task, making many more moves than necessary to reach the final goal position. The Multiple Errands Test taxes more everyday planning abilities. The test takes place in a shopping center, and the patient is required to perform various errands, such as obtaining a copy of the previous day's newspaper. The patients take much longer than control subjects. They go into inappropriate (irrelevant) shops as they pass them and repeatedly become distracted from their principal goal.

Impairments in planning might be related partly to difficulties evaluating the consequences of actions. Faced with a number of different, competing actions, patients

might not choose wisely because they are less sure of the consequences of those actions. Evidence for this arises from a "gambling" task (Fig. 50.4D). The patient has to choose cards from four different decks in an effort to win play money from the experimenter. Each card wins the patient some money, but some cards also lose money, and then the patient has to pay the experimenter. Unbeknownst to the patient, cards from the first two decks will win large amounts of money but are also occasionally associated with very large losses, and repeatedly choosing from these two decks will result in a net loss. By contrast, cards in the other two decks win smaller amounts of money, but the losses are also a lot smaller, and, overall, choosing from these two decks will result in a net profit. Control subjects initially choose from the two decks associated with the larger rewards, but after a few very large losses, they switch to choosing from the other decks and earn a profit. Patients with PFC damage also initially choose from the decks associated with larger rewards but then fail to alter their behavior until they lose all their money. This task is appealing because it is closely related to the types of problems that prefrontal patients experience in real life.

It was initially thought that PFC was only required when relatively complex decisions were required, like in the gambling task described previously. However, more recent findings have shown that PFC patients, particularly those with damage to the orbital PFC, are impaired even on extremely simple decisions. For example, if patients are shown two colored swatches and asked to pick their favorite, they appear to choose at random (Fellows & Farah, 2007). They seem to have a problem using their subjective preferences to guide their decisions. However, they can still solve perceptual decisions—for example, if you show them two colored swatches and ask them which is more blue. Therefore, it is thought that orbital PFC may be particularly important for value-based decision making—in other words, assigning a value to two options and then making your decision based on that value (Rangel, Camerer, & Montague, 2008).

Humans with Frontal Lobe Damage Have Impaired Working Memory

Patients might also have difficulties planning due to a problem with holding information in mind for a short while. This is the kind of short-term memory that one relies on when reading a phone number and then going to dial that number. This function is called working memory because the information is forgotten as soon as it is no longer relevant. The concept of working memory is influenced by the observation that monkeys with lesions of the PFC have deficits on a spatial delayed-response task that requires them to remember the location of a stimulus or behavioral response over a brief delay of several seconds. Early studies failed to find this deficit in humans with prefrontal damage, possibly because the patients verbalized the location of the stimulus (e.g., "It's on the left"), which presumably makes the task much easier. Later studies, however, in which the prefrontal damage was more extensive and bilateral did show a spatial delayed-response deficit. Other studies used abstract patterns that could not be easily verbally encoded and found that the patient's nonspatial working memory was also impaired.

Summary

We have seen that the PFC poses a complex problem. Damage to a relatively circumscribed region of cortex in humans produces a bewildering array of symptoms. But one caution in interpreting clinical studies concerns the size of the damage that typifies the prefrontal patient. Not only does the damage often encompass many different PFC regions, each of which may have different functions, but it also often encroaches onto neighboring regions, such as the premotor cortex, the cingulate cortex, and the insular cortex. Plus, it should be remembered that the PFC comprises many different anatomically defined areas, each possessing unique patterns of connections with the rest of the brain; it might be that each component of the dysexecutive syndrome arises from damage to different areas of the PFC. These matters are difficult to explore in humans with PFC damage, because the damage is typically so extensive that it encompasses many brain regions both within and external to the PFC. There are two solutions to this problem. The first is to use neuroimaging techniques, such as functional magnetic resonance imaging (fMRI), in healthy humans. This technique can detect areas of increased neuronal activity in specific brain regions with a resolution of 2–4 mm^3. A second method is to study the effects of experimentally produced focal lesions in monkeys. We will discuss each of these approaches in turn.

NEUROIMAGING STUDIES AND PFC

Neuroimaging studies have shown that many of the tasks with which patients with PFC damage struggle also activate PFC in healthy subjects. However, an advantage of the technique is that specific regions within PFC can be identified that are activated preferentially by specific cognitive processes. For example, fMRI studies show that performing the WCST activates ventrolateral PFC. In general, a number of trends have emerged from this field regarding the functional organization of PFC.

The clearest functional distinction is between orbitofrontal cortex and lateral PFC. Orbitofrontal cortex is consistently activated by tasks requiring the processing of

rewarding or emotional information. For example, it shows more activation to pleasant images (e.g., a baby's face) or unpleasant images (e.g., mutilated bodies) as opposed to neutral images. Similar results are seen in other modalities such as pleasant or unpleasant smells, tastes, sounds, and touches. Orbitofrontal cortex even responds to abstract rewards such as winning or losing money. Orbitofrontal cortex is not simply responding to the presence of these rewards, but seems to use this information to guide our decisions and choices. For example, orbitofrontal cortex is activated when subjects are choosing a meal from a menu, but not if they are simply reading the menu with no intention of ordering.

In contrast, lateral PFC is activated by a wide assortment of cognitive tasks. These include tests of inhibitory control (such as the Stroop task), rule switching tasks (such as the WCST), and working memory tasks. A distinction that has emerged from these studies concerns the respective roles of dorsolateral and ventrolateral PFC regions. Ventrolateral PFC is predominately activated by tasks that require holding information in working memory while dorsolateral PFC is activated when that information must be manipulated in some way. We return to this idea later in the chapter when we discuss the "multiple processing levels" theory of prefrontal function. Recently investigators have begun to focus on the most anterior portions of PFC, referred to as the "frontal pole," which corresponds to area 10. There is some evidence that this region might be responsible for controlling the transfer of information between dorsolateral and ventrolateral PFC.

In sum, neuroimaging studies have helped to show that we cannot consider the PFC as a single unitary area but that distinct subregions of PFC are responsible for carrying out specific processes. The clearest distinction is between the emotional and reward-based processing occurring in orbitofrontal cortex and the more cognitive processes occurring in lateral PFC. A problem with fMRI, however, is that while it can identify which regions are more active during a given task, it does not tell us whether those regions are *necessary* for the performance of the task. To determine whether a given PFC subregion is necessary for a specific cognitive process, findings from monkey neuropsychology are useful. We discuss these findings in the next section.

EFFECTS OF DAMAGE TO THE PREFRONTAL CORTEX IN MONKEYS

Studying the effects of experimentally induced lesions in monkeys has two advantages. First, because the lesions are experimentally induced, they can be small and focused on specific subregions of PFC. Second, they are a strong test of whether a specific subregion is necessary for the performance of a given cognitive task.

In 1935, Jacobsen published a seminal paper showing that lesions of the frontal lobe in monkeys produced deficits on a spatial delayed-response task. In this task, the monkey sees a reward hidden at one of two locations, and then after a brief delay is allowed to retrieve it (Fig. 50.5A). Monkeys with large PFC lesions behave as if they forgot where the reward was hidden, even after delays of just a few seconds. Subsequent experiments showed that lesions restricted to the dorsolateral PFC alone could produce the same deficit. By contrast, damage to the ventrolateral PFC impaired object delayed-response tasks. Monkeys with such damage have difficulty with delayed matching-to-sample (DMS) tasks in which they are shown an object (the sample) and then, after a brief delay of several seconds, must choose the same object (the match) from one or more nonmatching objects (Fig. 50.5B). The most severe deficits are observed when the same two objects are used repeatedly, requiring the monkey to remember which of the two objects it has seen most recently as the sample. Monkeys with orbital (ventral) PFC lesions tend to show the greatest deficit in tasks requiring reversal of previously successful actions. For example, they are impaired at spatial reversal tasks, in which the reward is alternated between two locations, (Fig. 50.5C) and object reversal tasks, in which a reward is alternated between each of two objects (Fig. 50.5D).

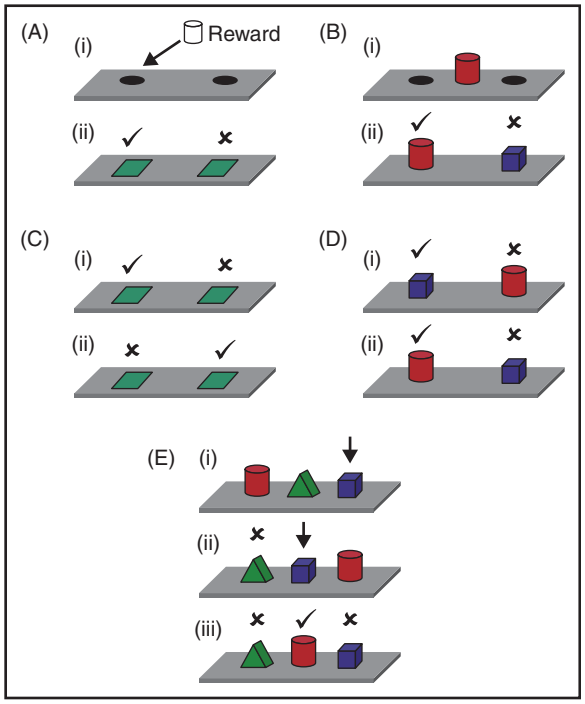

FIGURE 50.5 Some of the tasks on which monkeys with PFC damage are impaired. Check indicates correct choice, ✗ indicates incorrect choice. Arrow in E indicates monkey's choice in self-ordered task. (A) Spatial delayed response. (B) Delayed matching-to-sample. (C) Spatial reversal. (D) Object reversal. (E) Object self-ordered search task.

In both tasks the monkeys perseverate, continuing to choose the location or object under which the reward had first been hidden. Such observations led to the suggestion that the dorsal PFC might be responsible for processing spatial information, the ventral PFC for object-related information, and the orbital PFC for inhibitory control in accord with their preferential connections with the parietal, inferior temporal, and limbic system structures, respectively.

The picture, however, is not so simple and straightforward; a clear double dissociation between these impairments has not been demonstrated. Consider the hypothesized spatial versus object dissociation in the PFC. Dorsolateral PFC can impair performance on tasks that do not have a spatial component, such as object self-ordered search tasks. In this task the monkey is presented with three objects covering rewards. They must move each object in turn to get the reward, but after each choice, a screen is lowered and the object's positions are shuffled (Fig. 50.5E). Thus, the monkey must continually remember which of the three objects it has already checked for a reward. Neurophysiological studies paint a similar picture. While there may be some bias in the distribution of neurons that are sensitive to object identity or location in space (especially for the small population of highly specialized "face cells"), there is also a good deal of intermixing of neurons encoding these attributes, especially when the integration of these attributes is relevant to task performance. For more discussion of the issue of PFC functional topography, see Box 50.1.

Monkeys with PFC Damage Are Impaired on Rule-Based Tasks

We have already seen that humans with PFC damage have difficulties on tasks requiring the patient to use rules, such as the WCST (Fig. 50.4B). Marmosets were trained on a task similar to the WCST. They had to choose complex stimuli on the basis of a rule, such as "Choose by shape." When they were required to switch between different rules, monkeys with lesions of the dorsolateral PFC perseverated by continuing to choose on the basis of the previous rule, while monkeys with lesions of the orbital PFC were unimpaired. In contrast, when the same stimuli were used in an object reversal task, monkeys with lesions of the orbital PFC perseverated by continuing to choose the stimulus that had initially been rewarded, but the performance of monkeys with lesions of the dorsolateral PFC was normal. This suggests that both the dorsolateral and orbital PFC contribute to inhibitory control, but the dorsolateral PFC may be more engaged by inhibitory control over rules, while the orbital PFC may be more engaged by inhibitory control over choices based on objects and rewards.

Monkeys with frontal lobe damage also show deficits on simpler rule tasks, such as conditional learning. This requires the animal to solve a conditional problem of the form "If X, then Y"—for example, "If you see a red light, then move the lever to the right." Conditional learning requires associative relationships to be learned that are

BOX 50.1

FUNCTIONAL TOPOGRAPHY

Information about topography of neural properties in the PFC can provide important insights into its function. For example, knowing that primary visual cortex is organized into groups of neurons with similar tuning for orientation provides important clues to how it analyzes visual inputs. The anatomically complex nature of the PFC, coupled with the unique patterns of connections that each prefrontal area possesses, would certainly suggest a degree of functional fractionation. The clearest anatomical dissociation that has emerged is between the orbital and medial PFC regions and the lateral and dorsal PFC regions. Orbital and medial PFC areas are implicated in "hot" processes, such as motivation and emotion. Lateral and dorsal PFC areas implement "cool" cognitive processes, such as working memory and reasoning.

However, although there is this broad functional segregation, a more fine-grained functional topography has yet to be realized. One immediate problem that investigators face when trying to address this issue is that it is not clear how to subdivide cognitive processing. It is far easier to specify the sensory attributes of an apple than it is to list the different processes involved in planning or reasoning. In searching for this more fine-grained topography we should bear in mind two important points. First, PFC functional topography is likely to be based on broad categories or gradients of organization with overlap and intermixing of diverse information. Complex behavior requires that we recognize and respond to relationships across diverse dimensions, and representing these relationships is a prerequisite for cognitive control. Indeed, the majority of outputs of a given prefrontal area are to other prefrontal areas, so it is not surprising that many prefrontal neurons are multimodal. Second, because learning is central to cognitive control and modulates the properties of many PFC neurons (see Neurophysiology of the Prefrontal Cortex), it should have a large influence on PFC topography. Indeed, the flexible nature of controlled behaviors likely requires a dynamic anatomy, with neuronal properties changing to reflect the demands of the current task.

arbitrary and extend beyond the simple one-to-one mappings that underlie reflexive reactions. Whether or not a given response is successful depends on additional, contextual information. For example, reaching for popcorn can be rewarding, but only if one takes other information into account; if the popcorn belongs to another patron, the result could be disastrous. The need to take into account complex relationships in order to decide among alternative actions is presumably why cognitive control has evolved.

The advantage of using monkeys, however, is that the location and extent of the damage are under the control of the experimenter. This allows for more precise localization of the cortex necessary for a given process. This revealed that learning simple conditional rules seemed to depend on the premotor cortex immediately posterior to PFC, whereas learning more high-level abstract rules, of the kind tested by the WCST, involved dorsolateral PFC. Badre and colleagues showed that these findings extended to humans. Using fMRI, they showed that there was a posterior-anterior gradient in PFC, with progressively more abstract rules represented in progressively more anterior parts of PFC (Badre & D'Esposito, 2007). Conditional rules activated premotor cortex, rules based on stimulus dimensions (e.g., color or shape) activated dorsolateral prefrontal cortex, while rules based on the temporal context in which the task occurred activated the most anterior part of PFC, the frontal pole.

Monkeys with PFC Damage Show Emotional Impairments

Like humans, monkeys with PFC lesions, particularly in the orbitofrontal region, display marked changes in social and emotional behavior. Monkey society is dictated by a dominance hierarchy, and each monkey knows its place; a monkey is submissive to monkeys higher in the hierarchy (for example, the monkey grooms them) and is aggressive and threatening to monkeys lower in the hierarchy. Monkeys with PFC lesions, however, disregard this hierarchy and also decrease their interactions with troop members. This typically results in their being ostracized from the troop.

Current theories suggest that orbitofrontal cortex plays an important role in processing the value of sensory stimuli. For example, suppose that you learn that pressing the red button on a vending machine delivers chocolate, whereas pressing the green button delivers chips. Suppose also that you have just eaten a big bar of chocolate. The red button is now less valuable to you than the green button (since you are sick of chocolate!), and you are more likely to select the green button. Indeed, this is exactly how monkeys trained on a similar task behave. However, monkeys with damage to orbitofrontal cortex make choices more randomly, and their choices no longer appear to reflect the current value of the stimuli.

This inability to respond appropriately depending on the value of sensory stimuli could well underlie the social deficits that animals with orbitofrontal damage exhibit. Effective social behavior requires a constant monitoring of socially relevant stimuli. For example, paying attention to a person's facial expressions while you are speaking to them can yield all sorts of clues that you may need to modify what you are saying. They could look confused, upset, or angry. A failure to adjust to these cues would then be manifest as socially inappropriate behavior.

Recent results have also specified differences in the function of different parts of orbitofrontal cortex. Lateral orbitofrontal cortex is responsible for determining which outcome went with which stimulus, while the medial orbitofrontal cortex is responsible for comparing options and deciding which you would prefer (Walton, Behrens, Buckley, Rudebeck, & Rushworth, 2010). In the previous vending machine example, lateral orbitofrontal cortex would be responsible for storing the information about which button produces which food, while the medial orbitofrontal would be responsible for deciding which food you currently prefer. Together they can control which button you press. The authors also performed sophisticated behavioral analyses to show that dysfunction of these processes could produce perseverative deficits on reversal tasks (Figs. 50.5C, D). In other words, orbitofrontal cortex has little to do with inhibitory control. Rather the problems with reversal tasks that follow orbitofrontal damage reflect a more general problem in tracking which outcome was associated with which sensory stimulus.

Summary

Humans with damage to the PFC present a wide variety of symptoms, including a lack of inhibitory control, a shallowness of emotion, difficulty planning and organizing behavior, and impaired working memory. In general, they seem to have difficulty in exerting volitional control and organizing their mental processes and actions in order to direct them toward unseen goals. As a result, their behaviors are simple, reactive, and emitted without concern for future consequences.

Just like humans, monkeys with extensive prefrontal damage can appear remarkably unimpaired to the casual observer. They have no motoric impairments, and their ability to discriminate a variety of sensory stimuli remains intact. They are also capable of simple learning, such as Pavlovian and instrumental conditioning. However, they are impaired when behavioral demands extend beyond this to include additional task-specific constraints and/or involve overcoming a previously established response. Localizing a specific deficit to any one PFC subregion has proven difficult; double dissociations between different PFC regions are rare.

The pattern of deficits observed after PFC damage in humans and monkeys makes sense in light of the cognitive architecture depicted in Figure 50.2. The deficits seem to reflect a selective loss of higher-level functions. Lower-level, well-established routines are intact, but without the information about future goals and means provided by the higher-level functions, processing would be at the mercy of the environment. Behavior would be ruled by whatever sensory inputs happen to flow into the system and by whatever thoughts, emotions, and actions are strongly associated with these inputs. Behavior would seem impulsive and disinhibited, and emotional reactions inappropriate, because they would be emitted reflexively without any consideration of the future. Further, without the influence of future goals to continually drive task-appropriate processes, individuals would be distractible and would easily go "offtrack" when there are temporal gaps between sensory inputs, or between those inputs and the individual's responses.

NEUROPHYSIOLOGY OF THE PREFRONTAL CORTEX

PFC anatomy suggests it has the means for executive functions, and the effects on behavior after damage to the PFC support this idea. So do neurophysiological studies; they have shown that PFC neurons have the properties one would expect from a region intimately involved in goal-directed behavior.

The PFC Is Multimodal

PFC anatomy indicates that it is interconnected with many different brain systems, a prerequisite for cognitive control. This high degree of connectivity is reflected in the neural activity observed in the PFC. Its neurons are activated by visual, auditory, tactile, and gustatory stimulation (and their memory), as well as voluntary limb and eye movements. Further, these neurons seem capable of synthesizing this information in accord with task demands. For example, after monkeys are trained to make arm movements to visual and auditory targets appearing in different locations, many lateral PFC neurons are activated by both kinds of targets. Interestingly, few bimodal neurons were found in studies in which monkeys passively experienced visual and auditory stimuli. This finding suggests that task demands can exert a strong modulatory influence on PFC activity, which is consistent with its putative role in cognitive control.

PFC Neurons Can Sustain Their Activity

The first observations of PFC neural activity that were related to a cognitive process were made in the 1970s by Fuster, Niki, and their colleagues (Kubota & Niki, 1971; Fuster, 1973). Guided by lesion studies in monkeys, they recorded from the PFC while monkeys performed delayed-response tasks. They found that, during the memory delay, many PFC neurons showed sustained activity that seemed to keep information about a spatial or object cue online (Fig. 50.6). In spatial delayed-response tasks, cue-related "delay activity" could, in principle, reflect either sensory information related to the cue or movement information related to the behavioral response. Both are found in the PFC, each with different temporal characteristics. Sensory-related activity tends to be stronger nearer in time to the cue and then weakens as time passes, whereas movement-related neurons tend to increase their activity over time as the movement draws nearer. Goldman-Rakic (1987) and colleagues used a refined oculomotor version of the delayed-response task to demonstrate that dorsolateral PFC neurons have precise tuning for memories of particular visual field locations (Funahashi, Bruce, & Goldman-Rakic, 1989) (Fig. 50.7). They also demonstrated that PFC delay activity depends on dopamine receptors, a neurotransmitter implicated in signaling reinforcements and thus central to acquiring and sustaining goal-directed behaviors.

PFC delay activity has been shown to convey a wide range of behaviorally relevant cues: objects, colors, sounds, the frequency of a vibration to the hand, and forthcoming eye and arm movements. Similar activity is also evident in the sensory cortical areas and motor areas primarily responsible for analyzing inputs and generating behaviors, especially the higher-order areas that are

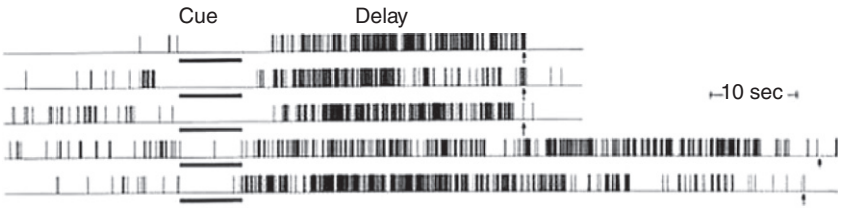

FIGURE 50.6 PFC delay activity. This figure shows the activity of a single PFC neuron during five trials of a spatial delayed response task. The arrow indicates the monkey's behavioral response at the end of the memory delay. Each small vertical line indicates an action potential from the neuron. Note the increased activity in the delay relative to other epochs. *From Fuster (1973).*

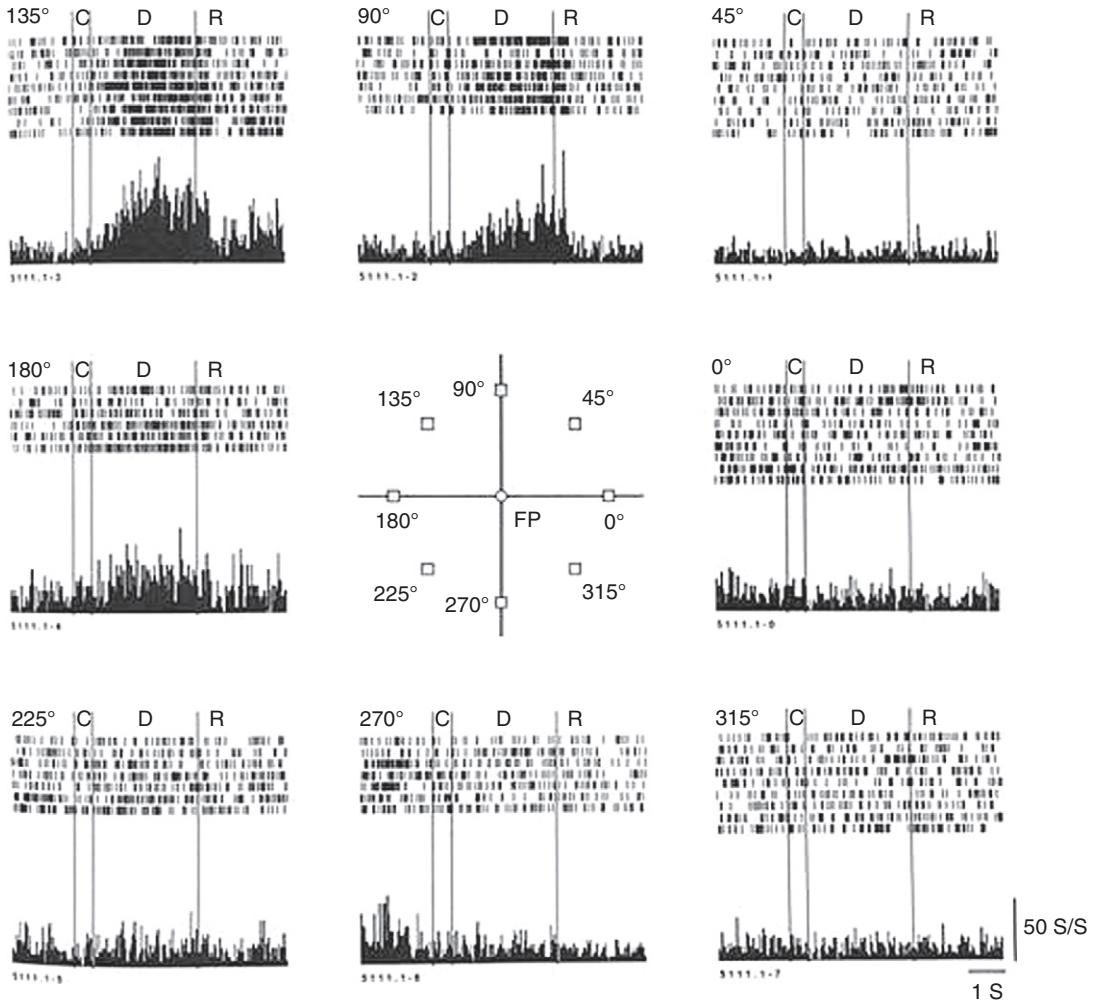

FIGURE 50.7 Activity of a single PFC neuron during performance of an oculomotor spatial delayed response task. Each trial starts with the monkey fixating the central fixation point (FP) indicated in the central diagram. After a delay (D), the monkey was allowed to respond by moving its eyes to the remembered location of the cue. Neural activity from cueing each location is shown by the corresponding histogram. The scale bars in the lower right indicate one second of time (1 S) and 50 spikes per second of neural activity (50 S/S). *From Funahashi et al. (1989).*

one or more steps removed from primary sensory and motor cortex. This is not surprising; sustained activity is apparent in many brain structures and must play a role in many neural processes. For example, it is likely to underlie iconic memory, the very brief lingering "afterimage" of recent sensory events. However, what separates more "cognitive" working memory processes from such lower-level processes as iconic memory is their ability to robustly sustain memories over potential distractions. PFC neurons do have this ability. For example, when monkeys are required to sustain the memory of a sample object across a delay period filled with visual distractors that require attention and processing, sustained activity within the prefrontal cortex can still maintain a memory of the sample object. By contrast, sustained activity in visual cortical areas seems more labile; it is disrupted by the presence of distractors. Following a distracting stimulus, neural activity reflects the distractor rather than the stimulus the monkey is retaining in working memory. This particular ability is not unique to the PFC. Some neurons in the entorhinal cortex, a region critical for memory, can also maintain sample-specific delay activity across intervening stimuli.

How does the PFC "latch" onto goal-relevant information and maintain it without disruption? Several models have been suggested. These typically employ a form of gating signal that instructs the PFC network when to maintain a given activity state. This gating signal may come from dopaminergic (DA) neurons in the midbrain. These neurons respond when monkeys are rewarded or, importantly, when monkeys can first predict that a reward is forthcoming. In many behavioral tasks, presentation of the cue at the start of the trial is a good predictor that reward is soon coming. Such a well-timed DA burst could strengthen current PFC representations, protecting them against interference

from disruption by irrelevant, distracting information until another DA influx reinforces another representation. Local injection of DA antagonists in the PFC does block delay activity in the PFC. The anatomical loops between the PFC and basal ganglia have been suggested to play a role here. Neural activity propagating around the loops may help sustain activity, and the basal ganglia have been suggested to provide a means by which DA signals can influence PFC activity. Box 50.2 describes the role of DA and PFC in Attention Deficit Hyperactivity Disorder.

PFC Neural Activity Reflects Task Rules

Playing the game requires knowing the rules. To explore how these rules might be represented in the PFC, experimenters manipulate task demands: monkeys are trained on tasks in which the physical cues are held constant while their behavioral meaning changes.

These studies suggest that PFC neurons represent task contingencies, the associative relationships that describe the logic needed to perform a task. Further support comes

BOX 50.2

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Do you pay attention to captivating yet irrelevant stimuli? Do you have trouble acting appropriately, fidgeting while listening to a lecture? Do you have difficulty planning and pursuing long-term goals? Do distractions knock you "off task"? When these not uncommon difficulties occur to a severe degree, they are symptoms of Attention Deficit Hyperactivity Disorder (ADHD), a disorder seen in children and adults. It is estimated that 3 to 5% of childen have this disorder, with about half retaining problems into adulthood. The symptoms of ADHD involve dysfunction of the prefrontal cortex (PFC) and its cortical and subcortical connections.

The criteria for diagnosis of ADHD include symptoms of "inattention" and "hyperactivity/impulsivity." Patients can have either the combined type, or predominantly "inattentive" or predominantly "hyperactive/impulsive" types. Many of the symptoms for "inattention" used to diagnose ADHD relate to attentional abilities of the PFC—for example, difficulty sustaining attention or organizing, easily distracted and forgetful. Similarly, many of the symptoms of "hyperactivity/impulsivity" describe PFC deficits—for example, difficulty awaiting turn. The PFC controls attention via its projections to the parietal and temporal cortices (see Chapter 49), while it controls motor responses via its projections to the motor cortices and striatum. These circuits appear to be impaired in patients with ADHD. ADHD symptoms are especially evident in "boring" settings that require endogenous rather than exogenous regulation of behavior. For example, ADHD children can sit still and play video games for hours, but have trouble attending in school. ADHD patients have difficulty sustaining a behavior or thought over a delay. As described in this chapter, PFC cells exhibit sustained firing over a delay which regulates thought and behavioral output.

Structural and functional imaging studies show consistent alterations in PFC-striatal-cerebellar circuits in ADHD patients. Volumetric measures have detected smaller right-sided PFC regions (the right side is most associated with attention, and the right inferior prefrontal cortex with behavioral inhibition; see Chapter 49). Changes in the size of the striatum also have been reported, and functional imaging studies have shown abnormal activity of both the PFC and striatum in ADHD patients performing tasks that require PFC inhibitory or attentional functions. Structural imaging studies also have shown consistent decreases in the size of the cerebellar vermis, a region that may exert regulatory influences on the noradrenergic (NE) cells of the locus coeruleus (LC) and the dopaminergic (DA) cells of the ventral tegmental area. These NE and DA cells in turn have profound influences on PFC-striatal circuitry (see following). Thus, a smaller vermis in ADHD patients may lead to impaired catecholamine inputs to PFC and striatum. Some evidence supports this idea: a neuroreceptor imaging study suggests there are reduced numbers of catecholamine terminals in the PFC of adults with ADHD.

NE and DA have a critical influence on PFC-striatal circuits, and thus changes in these inputs can have tremendous import on PFC cognitive functions. The current chapter describes how DA has an important effect on PFC function, and the same is true for NE. NE cells fire when a stimulus is of interest to the animal, releasing NE in the PFC. NE stimulates post-synaptic α_{2A}-adrenoceptors, enhancing delay-related firing and strengthening regulation of behavior and attention. This is accomplished by α_{2A}-adrenoceptor inhibition of cAMP production, resulting in the closure of HCN channels (Hyperpolarization-activated Cyclic Nucleotide-gated cation channels). HCN channels are co-localized with α_{2A}-adrenoceptors on the dendritic spines of PFC neurons in the superficial layers of PFC, especially on spine necks. Thus, α_{2A}-adrenoceptors are ideally localized to control the neurochemical microenvironment around these channels. When cAMP builds up, HCN channels open, and synaptic inputs onto the spines are effectively shunted, thus functionally disconnecting PFC neuronal networks. In contrast, when α_{2A}-adrenoceptor stimulation inhibits the production of cAMP, HCN channels are closed and the networks are able

BOX 50.2 (*cont'd*)

to connect to control attention and behavior. In contrast, very high levels of NE and DA, such as released during stressful conditions, can impair PFC function via excessive cAMP production (e.g., from very high levels of β1 and DA D1 receptor stimulation), and from activation of high levels of protein kinase C signaling initiated by NE α_1-adrenoceptor stimulation. Thus, the PFC has to have just the right neurochemical conditions to function optimally.

What causes ADHD? ADHD is highly heritable and has been linked with genetic alterations that interfere with NE or DA signaling. These linkages include the DA transporter; the D1, D5, and D4 receptors (the D4 receptor also has very high affinity for NE); the synthetic enzyme for NE (dopamine beta hydroxylase); and the α_{2A}-adrenoceptor. Environmental factors may also lead to disruption of PFC-striatal circuits. For example, some kinds of infection may lead to autoantibodies that attack PFC-striatal circuits, and perinatal injury may impact these circuits.

Medications for ADHD likely reduce symptoms of inattention and impulsivity by optimizing the neurochemical environment in the PFC and in the striatum. All effective treatments for ADHD interact with catecholamines: Stimulants such as Ritalin (methylphenidate) and Adderall (a mixture of amphetamines) increase NE and DA release and/or block catecholamine reuptake. Recent research in rats suggests that low, therapeutic doses of these compounds preferentially increase release in PFC and have a greater effect on the release of NE than DA. Consistent with these data, NE reuptake blockers are also used to treat ADHD (e.g., desipramine), including highly selective NE agents (atomoxetine, also known as Strattera). Drugs that mimic NE at α_{2A}-adrenoceptors (e.g., guanfacine) are effective, especially in decreasing impulsivity and distractibility. Wellbutrin (also known as Zyban or bupropion) is a DA reuptake blocker that is used to treat ADHD. How do these medications actually work to ameliorate ADHD symptoms? There have been several ideas proposed: (1) the etiology of ADHD involves insufficient catecholamine innervation of PFC-striatal circuits, and drugs that increase catecholamine receptor stimulation correct this; (2) ADHD involves excessive catecholamine release, and low doses of these medications correct this by promoting negative feedback, decreasing phasic catecholamine release; or (3) catecholamines are normal in ADHD patients (e.g., it is simply that their cortex is immature or inflamed), and amplification of catecholamine mechanisms enhances PFC function and reduces symptoms. Support for this latter idea arises from the fact that normal individuals are improved by small doses of these medications as well, such as when college students sometimes take low doses of stimulants to focus on writing a paper.

All of us experience PFC dysfunction as part of daily life, especially when we are tired or stressed. These effects are likely due to neurochemical changes—for example, in NE and DA—that have great impact on the functional integrity of the PFC. But for people with ADHD, dysfunction of the PFC is much more constant and often beyond their control. Perhaps it is this prevalence of PFC dysfunction in otherwise healthy individuals, and its association with stress, that lead to the dismissal of ADHD by some as not a real disorder. It is hoped that as we come to better understand the neurobiological bases of ADHD, we will gain a fuller perspective of ADHD and its symptoms.

from investigations that have shown that PFC activity reflects more complex task information such as rules. Monkeys can be taught to rapidly alternate between different rules. For example, following a given cue, they can learn to direct a response to either the cue's location (spatial matching rule) or an alternate location associated with the cue (associative rule), depending on which rule is currently in effect. When tested in this fashion, many PFC neurons show rule-specific activity (Fig. 50.8). For example, a PFC neuron might respond to a given visual cue when the monkey is using an associative rule but exhibit weak or no activity under identical sensory and attentional conditions that differed only in that the monkey was instead using a spatial rule. Such effects have been found in PFC for associative versus spatial rules, for object matching versus spatial matching versus associative rules, and for shape matching versus object matching rules (Asaad, Rainer, & Miller, 2000).

Primate behavior is not limited to following literal associations and specific rules. Primates can also abstract

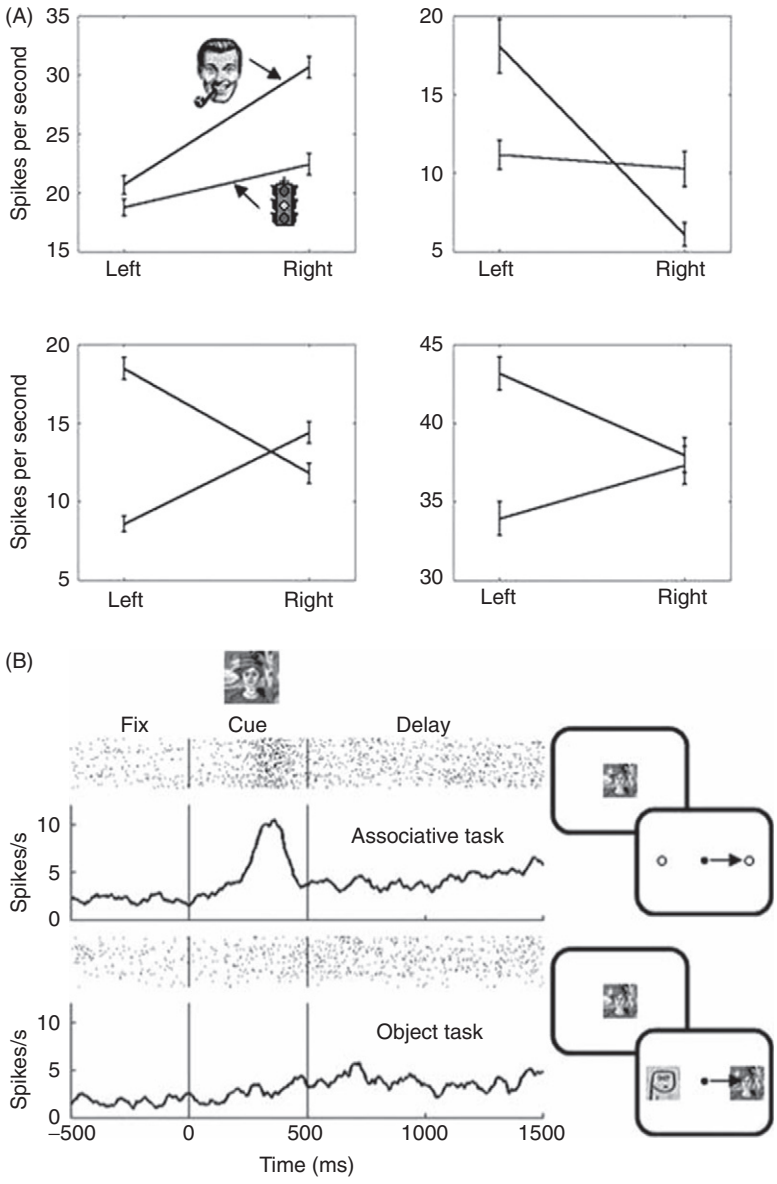

FIGURE 50.8 (A) The activity of four single PFC neurons when each of two objects, on different trials, instructed either a saccade to the right or a saccade to the left. The lines connect the average values obtained when a given object cued on the other saccade. The error bars show the standard error of the mean. Note that in each case, the neuron's activity depends on both the cue object and the saccade direction and that the tuning is nonlinear or conjunctive. That is, the level of activity to a given combination of object and saccade cannot be predicted from the neuron's response to the other combinations. (*Adapted from Asaad, Rainer, and Miller (1998)*). (B) A PFC neuron whose neural response to a cue object was highly dependent on the rule the monkey is currently using. The bottom half shows an example of a single PFC neuron's response to the same cue object during an object task (delayed matching to sample) and during an associative task (conditional visual motor). Note that the neuron is responsive to the cue during one task but not during the other, even though sensory stimulation is identical across the tasks. *Adapted from Asaad et al. (2000).*

general rules or principles, not tied to any particular stimulus or response. This ability allows behavior to extend beyond specific circumstances that have been directly experienced. For example, humans learn the "rules" for restaurant dining from specific experiences and can then generalize and apply them to new restaurants. Wallis, Anderson, and Miller (2001) investigated this process in monkeys by recording from single neurons in the PFC. Monkeys were trained to use two abstract rules; they indicated whether two successively presented pictures were either the same ("match") or different ("nonmatch"). The monkeys could perform this task with novel pictures, thus demonstrating that they had learned two general principles that could be applied to stimuli that they had not directly experienced. The most prevalent neuronal activity observed in the dorsolateral, ventrolateral, and orbital

PFC reflected the coding of the abstract "match" and "nonmatch" rules. This finding suggests that rule representation may be a cardinal PFC function. Recent findings using fMRI showed that humans also activate PFC when performing the exact same task.

PFC Neurons are Flexible

Another hallmark of primates is the ability to quickly learn new behaviors. PFC neurons are capable of a correspondingly rapid modification of their properties to meet task demands. For example, Cromer, Roy, and Miller (2010) trained monkeys to recognize two different and independent categorical distinctions (Cats vs. Dogs, Sports Cars vs. Sedans). They recorded neural activity from the PFC while monkeys switched back and forth between these categories. This revealed that many PFC neurons reflected *both* categorical distinctions. That is, the PFC neurons were category generalists that represent different, unrelated categories. This adaptability allows the brain to reutilize the same pool of neurons for different tasks. Further, this ability of PFC to multitask different types of information may be key to its role in rule learning. Without it, the PFC would quickly run out of capacity to learn new rules (Rigotti, Rubin, Wang, & Fusi, 2010). Neural network models suggest that having a large population of PFC neurons with mixed selectivity to diverse stimuli solves this capacity problem (Rigotti et al., 2010). Interestingly, neurons in the lateral intraparietal area (LIP) in posterior parietal cortex also seem to have this multitasking property (Fitzgerald et al., 2011), although it is not yet clear if those properties are generated with LIP or received from the PFC in a top-down fashion (see "Top-Down Control of Posterior Cortex by the PFC").

PFC Neurons Encode Rewards

Feedback about the consequences of actions is key to acquiring new goal-directed behaviors. Consequently, a large proportion of PFC neurons encode information about rewards, particularly in the orbitofrontal region. For example, some neurons are activated by the delivery of a reward, while others respond when an expected reward is not delivered. PFC neurons also encode the type of reward that the monkey expects to receive, for example a piece of cabbage versus a raisin, as well as the quantity of reward the monkey expects.

Recent evidence suggests that orbitofrontal neurons are in fact encoding a precise measure of the value of the reward. Determining this required overcoming an obvious hurdle: how does the experimenter determine how much an animal values a reward? One approach is through barter. If I want three chickens for my pig, then we can say that I find pigs three times more valuable than chickens. By bartering with a monkey using different types of juice, researchers showed that many orbitofrontal neurons encoded the value of one juice reward relative to another (Padoa-Schioppa, 2006). Orbitofrontal neurons also encode many other parameters that make one outcome more or less preferable. For example, they encode the delay until a reward is received, or the risk, probability or confidence that a reward will be received (Fig. 50.9). This has led to the suggestion that PFo may have a specialized role in encoding attributes that directly regulate the value of an outcome (Wallis, 2007). Consistent with this idea, PFo heavily connects with limbic areas responsible for processing reward information, such as the amygdala, nucleus accumbens, and hypothalamus, as well as gustatory and olfactory cortices, placing it in an excellent anatomical position to calculate the value of rewards.

Summary

As might be expected from a brain region suspected to orchestrate complex behavior, neural activity in the PFC conveys information about a wide range of external and internal information. But its activity is not limited to simple responses to sensory events or actions. Rather, the behavioral context has a pervasive influence on PFC activity. After training, many (up to half) dorsolateral, ventrolateral, and orbital PFC neurons encode information about the formal demands of behavior: contingencies between a wide range of stimuli, actions, and reward consequences, and behavior-guiding rules. By robustly sustaining their activity, PFC neurons can keep this and other behaviorally relevant information online to guide behaviors that extend over time. Also consistent with its role in guiding goal-directed behavior, PFC neurons process information about the expected results of achieving goals: rewards.

THEORIES OF PREFRONTAL CORTEX FUNCTION

Working Memory

One proposal is that the cardinal function of the PFC is to hold recent sensory inputs and movement-related information in active short-term memory, or working memory (Goldman-Rakic, 1987). In this view, the PFC acts as a temporary scratch pad that sustains the inputs it receives from other cortical areas. This hypothesis has its roots in observations of deficits in performance of delayed-response tasks following PFC damage and of PFC neurons that show sustained activity over a memory delay. Other deficits following PFC damage are thought to be sequelae of the working memory deficit. For example, patients might be impaired at planning because they are unable to keep in mind all the different variables that need to be considered. This in turn might make them appear disinhibited as

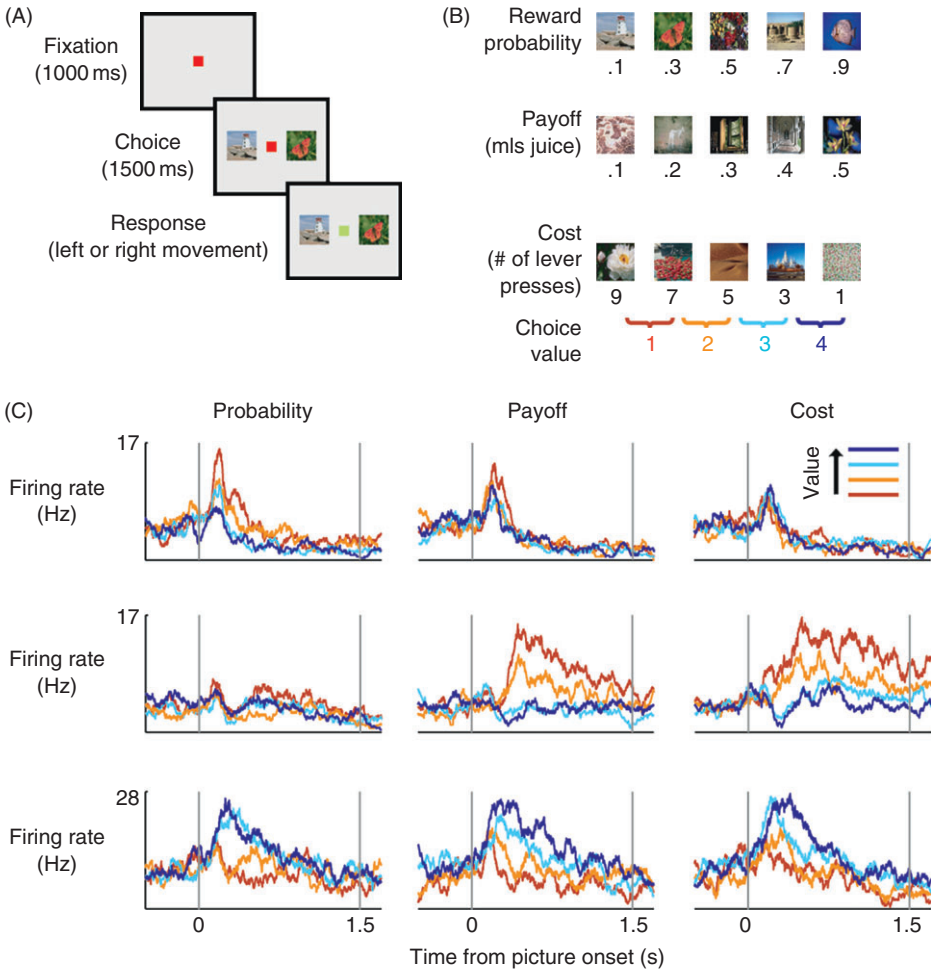

FIGURE 50.9 PFC neurons encode lots of information related to decisions. (A) The monkey was presented with two pictures and had to choose one. Each picture was associated with a specific outcome. (B) There were three sets of pictures. The probability picture set varied in terms of the likelihood of receiving a juice reward. The payoff picture set varied in terms of how much juice was associated with each picture. The cost picture set varied in terms of the number of lever presses necessary to earn the juice. Choice value indicates the choices that were used in the plots of neural activity. (C) Three neurons that encode different types of decision-related information. The top neuron encodes probability information. The second neuron encodes payoff and cost information. The bottom neuron encodes abstract value information that is independent of the precise type of decision. Some neurons encode increasing value, whereas other neurons encode decreasing value. *Adapted from Kennerely et al. (2009) with permission.*

their behavior becomes directed towards more immediate goals, rather than towards longer-term, more delayed goals.

Working memory maintenance functions are central to cognition; complex, goal-directed behaviors are typically drawn out and thus are impossible without mechanisms that extend information over time. There is ample evidence that these mechanisms are abundant in the PFC. Working memory is unlikely to be the whole story, however. Many of the tasks on which prefrontal patients and monkeys show impairment do not have an obvious working memory component, such as the WCST and reversal tasks.

Recent studies have explicitly investigated this issue, by examining the performance of monkeys with lesions of the ventrolateral PFC on a simultaneous color-matching task. In this task the monkey is presented with a sample color and two test colors simultaneously. The monkey must choose the test color that matches the sample color. PFC lesioned monkeys were impaired at this task, despite the fact the task involved contains no delays and therefore no working memory requirements. The task does, however, require conditional rules (e.g., "If the sample color is red, then choose the red test stimulus"), and the role of the PFC in the representation of such rules (see following) might explain this impairment.

Somatic Marker Hypothesis

It has been suggested that the orbital PFC is responsible for labeling people, objects, or situations with an "affective significance" (Damasio, 1994). This is achieved by associating memories of past, affectively laden events with a representation of the somatic state that the event evoked. Thus, the memory of the past event is labeled with a "somatic marker" that helps individuals make decisions. Rather than having to evaluate all the pros and cons of prior circumstances to decide on the present, one can simply recall the associated somatic marker, providing the individual with the appropriate affective state and, in effect, a "gut-feeling" of which alternative is correct. Patients with damage to this system might be unable to reach a decision, simply because they become incapacitated by contemplating irrelevant information. None of the outcomes of their actions will be obviously more

emotionally preferable than alternative outcomes, and patients might make decisions randomly or impulsively and as such appear to be disinhibited.

A deficient somatic marker system would explain the impairments that patients with damage to the orbitofrontal PFC exhibit on the "gambling task" (Fig. 50.6D). The reward contingencies associated with each deck of cards are designed to be too complex to be ascertained purely by logical reasoning. Control subjects succeed at the task because they associate a somatic marker with each deck of cards, warning the subject as to whether the choice they are about to make is risky. Further support comes from measures of skin conductance responses (SCRs) that reflect autonomic nervous system processing. Control subjects show SCRs prior to the selection of a card, and choices from risky decks are preceded by a larger SCR than choices from less risky decks. Patients with damage to the ventromedial PFC showed no anticipatory SCRs, although their SCRs when actually receiving the reward or punishment are intact.

This hypothesis is similar to one advanced by William James in the nineteenth century. He proposed that emotional feelings depend on feedback from the autonomic nervous system. For instance, running from a bear because we are afraid evokes a particular autonomic state (such as increased heart rate and blood pressure) that makes us feel afraid. Thus, as James stated, we do not run because we are afraid, but we are afraid because we run. A problem with simply using autonomic nervous system signals, however, is that autonomic states produced by different emotions can be identical. Later studies showed that manipulations of the autonomic nervous system, for example, by administering adrenaline, could alter the magnitude but not necessarily the type of emotion experienced in human subjects. These problems are avoided if the orbitofrontal cortex does not need to access the autonomic nervous system directly, but rather can use a conditioned association between the autonomic state and various cortical representations. For example, associations with the somatosensory cortex may be involved in emotional interpretations; patients with damage to the somatosensory cortex have difficulty recognizing facial emotions as do patients with orbital frontal damage.

Multiple Processing Levels

It has been proposed that the PFC is organized by level of processing, much as there are primary and higher-order sensory cortices (Petrides, 1996). The ventrolateral PFC is primary. It receives inputs from sensory cortex and is responsible for their simple maintenance in working memory and for retrieval of information from long-term memory. The dorsolateral PFC then takes this information and performs more executive processes, such as monitoring multiple behaviors and manipulating information. For example, simply rehearsing a phone number is a ventrolateral PFC function, while saying that same number backward is a dorsolateral PFC function. It should be noted that such an arrangement would preclude the possibility of demonstrating a functional double dissociation between these two areas, since the dorsolateral PFC is only able to perform executive processes on information after it had been received by the ventrolateral PFC. Thus, removing the dorsolateral PFC would impair the higher-level processes, while removing the ventrolateral PFC would impair both.

This hypothesis has been supported by evidence from neuroimaging in humans. Subjects were required to perform five spatial working memory tasks while they were scanned using positron emission tomography. This technique enables the visualization of areas of the brain with the increased blood flow that is related to neural activity. Two of the tasks had simple maintenance requirements; they activated the ventrolateral PFC. The three other tasks also had manipulation requirements and they activated the dorsolateral PFC.

Rule Representation and Hierarchical Organization

Several investigators have pointed out that because knowledge about goals, means, and consequences is vital to planning and implementing complex goal-directed behavior, the PFC is likely to play a central role in its acquisition and representation. The neural instantiation of task demands in the PFC was first proposed by Joaquin Fuster (1989). Based on behavioral and neurophysiological experiments in monkeys, he hypothesized that sustained activity in the PFC was not used merely to retain recent sensory events but also to link together behavioral relevant, but temporally separate, events and actions into a representation of task contingencies.

Other investigators have reached similar conclusions. Grafman (1994) suggested that the PFC contains managerial knowledge units (MKUs), sets of task contingencies linked under common themes that can be flexibly combined into extended routines. An MKU may describe the expected events and appropriate responses for dining in a restaurant, for example. Passingham (1993) suggested that many of the deficits following PFC damage can be explained by a loss of the ability to acquire conditional if-then rules. Wise, Murray, and Gerfen (1996) proposed complementary roles in rule learning for the PFC and the basal ganglia. The PFC is thought to act when new rules are learned while the basal ganglia is thought to potentiate (select) the previously learned rules that are appropriate for the current situation.

Cognitive control has also been studied by developing simulated neural network models that can perform tasks that depend on controlled processing, such as the

Stroop Test. These models invariably include units dedicated to representing task rules and contingencies. Analogies are often drawn between these units and the PFC.

How might the PFC acquire rule information and use it for cognitive control? Miller and Cohen (2001) proposed that reward signals from midbrain dopamine systems act on the multimodal circuitry in the PFC to strengthen connections between neurons that process the information that led to the reward. This action results in a model of the task contingencies, which in neural terms amounts to a representation of the pattern of connections among the sensory, motor, and mnemonic representations needed to solve that task. Maintenance mechanisms in the PFC sustain this representation during task performance. This produces feedback signals to posterior cortex that bias the flow of activity along lines that match the PFC representation, i.e. along task-relevant neural pathways. In short, the PFC plots a "map" of which neural pathways in the forebrain are successful at solving a task and then holds it online in the PFC so that the rest of the neocortex can follow it.

Evidence for this proposal comes from the finding that PFC neurons show neural activity that reflects behaviorally relevant associations between disparate and arbitrary events and actions, behavioral context, and rules. Behavioral and neurophysiological studies of focal attention also point to the operation of top-down signals on the visual cortex (presumed to come from the PFC) that enhance representations of behaviorally relevant stimuli and visual field locations at the expense of irrelevant ones. Evidence that such signals come from the PFC was supported by a recent observation that disconnecting the PFC from the temporal cortex prevented the activation of stored memories in the latter and caused monkeys to fail at a recall test (Tomita, Ohbayashi, Nakahara, Hasegawa, & Miyashita, 1999).

Recent work has begun to look at how the representation of rules is organized in PFC. The picture that is emerging from these studies is that more abstract information is represented by progressively more abstract regions of PFC (Badre & D'Esposito, 2007). Neuroimaging studies show that simple associations between specific stimuli and specific motor responses (e.g., if red light, then stop) are encoded by areas immediately posterior to PFC in the premotor cortex. Lateral PFC regions are activated as rules become more abstract, for example, dependent on abstract stimulus properties such as shape or color. Finally, the most anterior parts of PFC are activated when rules are dependent on the context in which they occur, whether that context is defined temporally, spatially, or relationally.

These findings suggest that rules may be organized hierarchically within PFC. In a hierarchical organization, information at higher levels of the hierarchy is dependent on lower levels. Studies of patients with damage to different parts of PFC suggest that this is, indeed, the case (Badre, Hoffman, Cooney, & D'Esposito, 2009). Damage to anterior PFC only impairs the highest level of the hierarchy (contextual rules). Damage to lateral PFC impairs contextual rules and rules based on abstract stimulus properties, but leaves intact specific-response associations. Finally, damage to premotor cortex impairs all types of rule implementation. Recent computational models have shown how reinforcement learning rules, thought to be encoded by dopamine neurons, could lead to the development of hierarchical representations (Botvinick, Niv, & Barto, 2009; Frank & Badre, 2011).

The Flexibility and Limited Capacity of Controlled Processing

Sustained activation is central in many views of PFC functions. This is not surprising considering the importance of working memory for cognitive control and that sustained activity is common in the PFC. But as O'Reilly and Munakata (2000) have pointed out, representing information through sustained activity offers more than just the ability to bridge gaps; it has other advantages for cognitive control.

It is universally assumed that long-term storage in the brain depends on changing synaptic weights, by strengthening some neural connections and weakening others. Encoding information in structural changes has obvious advantages for long-term storage but the resulting memories are relatively inflexible. Also, changing synaptic weights has local effects; only the two neurons sharing the synapse are affected. The information contained in a set of synaptic weights is thus expressed only when the circuit is fired. By contrast, the information needed to guide goal-directed behavior must be expressed in a format that allows it to affect the ongoing processing in other brain systems. Sustained activity is such a format. It is extended over time and information contained in a pattern of activity can be propagated across the brain. Thus, the ability of sustained activity to tonically influence other brain systems is likely important for coordinating diverse processing around a specific goal. It also affords flexibility; if cognitive control stems from a pattern of information maintained in the PFC, changing behavior is as easy as changing the pattern (O'Reilly & Munakata, 2000; Miller & Cohen, 2001).

Finally, the neuronal mechanisms by which information needed for cognitive control is expressed might explain the severely limited capacity of controlled processes. A vast amount of information can be stored by changing synaptic weights of a network that contains many neurons, each with many potential connections. At any given time, however, most of this information is latent; it is expressed only when the relevant circuit is activated. By contrast, if the information for cognitive control

is expressed in a unique pattern of ongoing activity distributed across many simultaneously active neurons—a population code—then there will be a natural capacity limitation. Trying to represent more than just a few items at the same time would degrade information because the unique patterns impinging on a given set of neurons would overwrite and interfere with one another.

The PFC versus the Basal Ganglia: Model-Building versus "Snapshots"

The prefrontal cortex (and other frontal cortical areas) forms anatomical loops with the basal ganglia (BG), a set of subcortical structures that have motor and learning functions (see Chapter 30). Different regions of the frontal lobe (e.g., the lateral PFC, orbital PFC, premotor cortex) have anatomically segregated loops with the BG that are "closed," meaning that the same region of the frontal cortex that gives rise to the loop is also the target of that loop via BG's connections with the thalamus. Closed loops are noteworthy because they may allow recursive processing in which the results of processing are fed back into the loop for further elaboration. It is possible, if not likely, that some form of recursive processing is responsible for the open-ended nature of advanced thought.

Daw and colleagues (2005) suggested functional specializations for the PFC and BG (specifically the striatum, the BG structure that receives input from the cerebral cortex). They suggested that the PFC builds models of an entire behavior; it retains information about the overall structure of the task, following the whole course of action from initial state to ultimate outcome. They liken this to a "tree" structure for a typical operant task: behaviors begin in an initial state with two or more possible response alternatives. Choosing one response leads to another state with new response alternatives, with this process continuing throughout the task, ultimately leading to a reward. The PFC is able to capture this entire tree structure, essentially providing the animal with an internal model of the task. By contrast, the striatum is thought to learn the task piecemeal, with each state's response alternatives individually captured as separate "frames." This "caching reinforcement learning" system retains information about which alternative is "better" in each state but nothing about the overall structure of the task (i.e., the whole tree). In short, the BG learns each fork in the road, while the PFC puts together the whole route.

This is thought to explain observations of tasks that use reinforcer devaluation. In such tasks, you change the value of the reward by saturating the animal on a given reward (for example, overfeeding on chocolate if chocolate is a reward on that task). This has revealed two classes of behavior. Behaviors that are affected by reinforcer devaluation are considered to be goal-directed because changing the goal changes the behavior. As discussed above, goal-directed behaviors depend on the PFC. By contrast, overlearned behaviors whose outcomes remain relatively constant can become habits, impervious to reinforcer devaluation. Because these behaviors are not affected by changing the goal, they seem to reflect control by a frame-based caching system in which the propensity for a given alternative in each situation is stored independently of information about past or future states. Indeed, such a piecemeal caching system could only acquire complex tasks as habits because it can only learn them if they are always conducted in the same fashion. Habits have long been thought to be a specialization of the BG.

Support for this model comes from recent observations that during conditional visuomotor rule learning, the dorsal striatum of the BG (the portion that receives direct projections from the lateral PFC and whose output ultimately loops back to the lateral PFC) showed very fast, almost bi-stable changes in neural activity (Pasupathy & Miller, 2005). By contrast, the lateral PFC showed slower gradual changes in neural activity. This may reflect the much heavier input from midbrain dopaminergic reward-related neurons in the striatum than the PFC. The fast plasticity in the striatum could be ideal for learning the reinforcement-related snapshots that capture the immediate circumstances and which alternative is preferable for a particular state. The slow plasticity in the PFC is better suited for the linking in of additional information about past states that is needed to learn and retain an entire model of the task and thus predict future states.

Top-Down Control of Posterior Cortex by the PFC

The theories discussed above all either tacitly or explicitly assume that the PFC is the provider of top-down control that modulates processing in other brain areas biasing it toward task-relevant information. Depending on the brain system that receives those signals, the result could be attention, memory retrieval, or motor control. Due to the technological difficulty in directly measuring how different brain structures interact, most of the evidence for this has been indirect. Recent work, however, has provided some direct evidence, mainly from studies of visual attention.

For example, Tirin Moore and colleagues have found that stimulating FEF neurons at subthreshold levels (i.e., levels that would not elicit an eye movement) induces attention-like effects in V4 neurons whose receptive fields overlap with the FEF stimulation sites (Moore & Armstrong, 2003). Dopamine may play an important role in the allocation of attention, as stimulating dopamine D1R receptors in FEF leads to attention-like effects (Noudoost & Moore, 2011). These results suggest that

FEF, which is known to play a role in generating volitional eye movements, may also play a direct role in top-down direction of attention.

Further support comes from simultaneous multielectrode recording from the PFC and posterior cortex. Multiple electrodes allow detailed examination of neural latencies and synchrony between neurons that gives insight into network properties and the flow of neural activity (Miller & Wilson, 2008). For example, both the PFC and an area of the parietal cortex called the lateral intraparietal area (LIP) are thought to play roles in focusing visual attention. Simultaneous recording from them while monkeys volitional searched a display for a target object (i.e., in a top-down fashion), neurons in the PFC reflected the shift of attention to the target before LIP (Buschman & Miller, 2007). By contrast, when the target was more salient than other stimuli and the monkey's attention was reflexively drawn to it (i.e., in a bottom-up or sensory-driven fashion), the shift of attention to the target was reflected first in LIP. The timing of appearance of these signals in the two areas suggests that the top-down control signals originated in the prefrontal cortex and then flowed posteriorly to LIP whereas bottom-up sensory signals flowed the opposite direction (Fig. 50.10).

Synchronized, rhythmic oscillations between brain areas may also play a role in top-down control. These "brain waves" are thought, among other things, to facilitate long-range communication between brain areas. When neurons are simultaneously depolarized, they are more susceptible to influence from each other (conversely, when they are out of phase, they are less likely to communicate). Long-range oscillatory coherence is found, for example, between the PFC and LIP during shifts of attention (Buschman & Miller, 2007). Desimone and colleagues paired recordings at the posterior end of the PFC, in the frontal eye fields (FEF), with visual cortical area V4 and found that focusing attention on a visual stimulus increased high frequency coupling between them (Gregoriou, Gotts, Zhou, & Desimone, 2009). The time-shift of their coupling suggested that the coupling was initiated by the FEF. Such long-range oscillations may dynamically sculpt subnetworks out of the greater number of anatomical connections. Thus, they may help direct top-down signals to specific neuron populations.

Summary

The ability to take charge of one's actions and direct them toward future aims is called cognitive control. Virtually all theories of cognition posit that cognition depends on functions specialized for the acquisition of information about goals and means. These functions exert a top-down influence on the lower-level automatic processes that mediate sensory analysis, memory storage, and motor outputs, orchestrating and directing them toward a given goal.

The PFC, a brain structure that reaches its greatest complexity in the primate brain, seems to play a central role in cognitive control. It has the requisite anatomical infrastructure. It has access to, and the means to influence processing in, all major forebrain systems and can provide a means to synthesize the diverse information related to a given goal. Indeed, its damage in humans and monkeys results in a dysexecutive syndrome; individuals are stimulus-bound and seem capable only of reacting to the immediate environment. Information about unseen goals and potential consequences of actions has little influence on behavior. PFC neurons also have properties consistent with their participation in cognitive control: they are multimodal, reflect task demands, and can sustain their activity to keep task-relevant information online during task performance.

Theories of PFC function suggest that it makes several contributions important for cognitive control: maintenance and manipulation of information in working memory, the assignment and recall of the affective tags related to different choices, and the acquisition and representation of behavior-guiding rules that help orchestrate goal-directed behaviors. None of these theories is mutually exclusive, and indeed, different theories may be focusing on different aspects of a complex system that is involved in a wide range of brain processes.

CHAPTER

51

The Neuroscience of Consciousness

Consciousness is one of the most enigmatic features of the universe. People—and presumably many other animals, too—not only act but feel: they see, hear, smell, recall, plan for the future. These activities are associated with subjective, ineffable, immaterial feelings that are tied in some manner to the material brain. The exact nature of this relationship—the classical mind-body problem—remains elusive and the subject of heated debate. These firsthand, subjective experiences pose a daunting challenge to the scientific method that has, in many other areas, proven so immensely fruitful. Science can describe events microseconds following the Big Bang, offer an increasingly detailed account of matter and how to manipulate it, and uncover the biophysical and neurophysiological nuts and bolts of the brain and its pathologies. However, this same method has as yet failed to provide a satisfactory account of how firsthand, subjective experience fits into the objective, physical universe. The brute fact of consciousness comes as a total surprise; it does not appear to follow from any phenomena in physics or biology. Indeed, some modern philosophers argue that consciousness is not logically supervenient to physics (Chalmers, 1996). That is, it is certainly logically possible to imagine a world identical to ours but without any conscious experience. Nothing in the known laws of physics—or of biology—seems to contradict this. Yet we do find ourselves in a world where each one of us has conscious experiences, sees a picture of the world and so on.

People willingly concede that when it comes to nuclear physics or molecular biology, specialist knowledge is essential; but many assume that there are few relevant facts about consciousness and therefore everybody is entitled to their own theory. Nothing could be further from the truth. There is an immense amount of relevant psychological, clinical, and neuroscientific data and observations that must be accounted for. Furthermore, the modern focus on the neuronal basis of consciousness in the brain—rather than on interminable philosophical debates—has given brain scientists tools to greatly increase our knowledge of the conscious mind.

Consciousness is a state-dependent property of certain types of complex, biological, adaptive, and highly interconnected systems. The best example of consciousness is found in a healthy and attentive human brain—for example, the reader of this chapter. Not all biological, adaptive systems appear to have consciousness; examples include the enteric nervous system and the immune system. Brain scientists are exploiting a number of empirical approaches that shed light on the neural basis of consciousness. This chapter reviews these approaches and summarizes what has been learned.

WHAT PHENOMENA DOES CONSCIOUSNESS ENCOMPASS?

There are many definitions of *consciousness* (Searle, 2004). A common philosophical one is "*Consciousness is what it is like to be something*," such as the experience of what it feels like to see red, to be me, or to be angry. This what-it-feels-like-from-within definition expresses the principal irreducible characteristic of the phenomenal aspect of consciousness: *to experience something*. "What it feels like to see red" also emphasizes the subjective or *first-person perspective* of consciousness: it is a subject, an I, who is having the experiences, and the experience is inevitably private.

A science of consciousness must explain the exact relationship between phenomenal, mental states, and brain states. This is the heart of the classical mind-body

© 2013 Elsevier Inc. All rights reserved.

problem: *What is the nature of the relationship between the immaterial, conscious mind and its physical basis in the electrochemical interactions in the body?* This problem can be divided into several subproblems:

1. Why is there any experience at all? Or, put differently, why does any one brain state—that is, neurons over here firing, while neurons over there remain silent—feel like anything? In philosophy, this is referred to by some as the *Hard Problem* (note the capitalization), or as the explanatory gap between the material, objective world and the subjective, phenomenal world (Chalmers, 1996). Many scholars have argued that the exact nature of this relationship will remain a central puzzle of human existence, without an adequate reductionistic, scientific explanation. However, as similar sentiments have been expressed in the past for the problem of seeking to understand life or to determine what material the stars are made out of, it is best to put this question aside for the moment and not be taken in by defeatist arguments.
2. Why is the relationship among different experiences the way it is? For instance, red, yellow, green, cyan, blue, and magenta are all colors that can be mapped onto the topology of a circle. Why? Furthermore, as a group, these color percepts share certain commonalities that make them different from other percepts, such as seeing motion or smelling a rose.
3. Why are feelings private? As expressed by poets and novelists, we cannot communicate an experience to somebody else except by way of example. Try explaining vision to somebody blind from birth, or color to an achromat—rare individuals born without any cone photoreceptors.
4. How do feelings acquire meaning? Subjective states are not abstract states but have an immense amount of associated explicit and implicit feelings. Think of the unmistakable smell of dogs coming in from the rain or the crunchy texture of potato chips.
5. Why are only some behaviors associated with conscious states? Much brain activity and associated behavior occur without any conscious sensation.
6. What is the function—if any—of conscious experiences?

THE NEUROBIOLOGY OF FREE WILL

A further aspect of the mind-body problem is the question of free will, a vast topic. Answering this question goes to the heart of the way people think of themselves. The spectrum of views ranges from the traditional and deeply embedded belief that we are free, autonomous, and conscious actors to the view that we are biological machines driven by needs and desires beyond conscious access and with limited insight or voluntary control.

Of great relevance are the classical findings by Libet, Gleason, Wright, and Pearl (1983) of brain events that precede the conscious initiation of a voluntary action. In this seminal experiment, subjects were sitting in front of an oscilloscope, tracking a spot of light moving every 2.56 seconds around a circle. Every now and then, "spontaneously," the subject had to carry out a specific voluntary action, here flexing their wrist. If this action is repeated sufficiently often while electrical activity around the vertex of the head is recorded, a *readiness potential* (*Bereitschaftspotential*) in the form of a sustained scalp negativity develops 1–2 sec before the muscle starts to move. Libet asked subjects to silently note the position of the spot of light when they first "felt the urge" to flex their wrist and to report this location afterward. This temporal marker for the awareness of willing an action occurs on average 200 msec before initiation of muscular action (with a standard error of about 20 msec), in accordance with commonsense notions of the causal action of free will. However, the readiness potential can be detected at least 350 msec before awareness of the action. In other words, the subject's brain signals the action at least half a second before the subject feels that he or she has initiated it!

The original experiment has been replicated (Haggard & Eimer, 1999) as well as extended using fMRI, where precentral and parietal cortices can signal decisions up to ten seconds prior to entering awareness. Yet, because of its counterintuitive implication that conscious will has no causal role, the interpretation of these experiments continues to be vigorously debated (Haggard, 2008).

Psychological work in normal individuals and in patients reveals further dissociations between the conscious perception of a willed action and its actual execution: subjects believe that they perform actions that they did not do, while, under different circumstances, subjects feel that they are not responsible for actions that are, demonstrably, their own (Haggard, 2008; Wegner, 2002).

Yet whether volition is illusory or is free in some libertarian sense does not answer the question of how subjective states relate to brain states. The perception of free will, what psychologists call the *feeling of agency* or *authorship* (e.g., "I decided to lift my finger"), is a subjective state with an associated quale no different in kind from the quale of a toothache or seeing marine blue. So even if free will is a complete chimera, the subjective feeling of willing an action must have some neuronal correlate.

The quiddity of the sensation of agency has been strengthened by direct electrical brain stimulation during neurosurgery and fMRI experiments. These implicate posterior parietal, medial pre-motor and anterior cingulate cortices in generating the subjective feeling of triggering an action (Desmurgert et al., 2009; Haggard, 2008). In other words, the neural correlate for the feeling of apparent causation involves activity in these regions.

CONSCIOUSNESS IN OTHER SPECIES

Data about subjective states come not only from people who can talk about their subjective experiences but also from nonlinguistic competent individuals—such as newborn babies or patients with complete paralysis of nearly all voluntary muscles (locked-in syndrome)—and, most importantly, from animals other than humans. There are three reasons to assume that many species, in particular those with complex behaviors such as mammals, share at least some aspects of consciousness with humans:

1. *Similar neuronal architecture:* Except for size, there are no large-scale genomic, architectonic, cellular, or neurophysiological differences between the cerebral cortex and thalamus of mice, monkeys, humans, and whales. They are not the same and obey slightly different anatomical scaling laws but are overall remarkably similar (Herculano-Houzel, 2009).
2. *Similar behavior:* Almost all human behaviors have precursors in the animal literature. Take the case of pain. The behaviors seen in humans when they experience pain and distress—facial contortions, moaning, yelping, or other forms of vocalization; motor activity such as writhing; avoidance behaviors at the prospect of a repetition of the painful stimulus—can be observed in all mammals and in many other species. Likewise for the physiological signals that attend pain—activation of the sympathetic autonomous nervous system, resulting in change in blood pressure, dilated pupils, sweating, increased heart rate, release of stress hormones, and so on. The discovery of cortical pain responses in premature babies (Slater et al., 2006) and of empathy and observational pain in mice (Jeon et al., 2010) shows the fallacy of relying on language as sole criteria for consciousness.
3. *Evolutionary continuity:* The first true mammals appeared at the end of the Triassic period, about 220 million years ago, with primates proliferating following the Cretaceous-Tertiary extinction event, about 60 million years ago, while humans and macaque monkeys did not diverge until 30 million years ago (Allman, 1999). *Homo sapiens* is part of an evolutionary continuum with its implied structural and behavioral continuity, rather than an independently developed organism.

While certain aspects of consciousness, in particular those relating to the self, introspection and to abstract, culturally transmitted knowledge, may not be widespread in nonhuman animals, there is little reason to doubt that other mammals share conscious feelings—sentience—with humans. To believe that humans are special, are singled out by the gift of consciousness above all other species, is a remnant of humanity's atavistic, deeply held belief that *Homo sapiens* occupies a privileged place in the universe, a belief with no empirical basis.

The extent to which nonmammalian vertebrates, such as tuna, cichlid, and other fish; crows, ravens, magpies, parrots, and other birds; or even invertebrates, such as squids or bees, with complex, nonstereotyped behaviors including delayed-matching, non-matching-to-sample, and other forms of learning (Giurfa, Zhang, Jenett, Menzel, & Srinivasan, 2001) are conscious is difficult to answer at this point in time. Without a sounder understanding of the neuronal architecture necessary to support consciousness, it is unclear where in the animal kingdom to draw the Rubicon that separates species with at least some conscious percepts from those that never experience anything and that are nothing but pure automata (Edelman, Baars, & Seth, 2005, Koch, 2012).

AROUSAL AND STATES OF CONSCIOUSNESS

There are two quite distinct meanings of *being conscious*, relating to the intransitive and to the transitive usage of the verb. The former revolves around *arousal* and *states of consciousness*, while the latter deals with *the content of consciousness* and *conscious states*.

To be conscious of anything, the brain must be in a relatively high state of arousal. This is as true of wakefulness as it is of REM sleep that can be vividly, consciously experienced—though usually not remembered—in dreams (see Chapter 40). The level of brain arousal, measured by electrical or metabolic brain activity, fluctuates in a circadian manner, and is influenced by lack of sleep, drugs and alcohol, physical exertion, and so on in a predictable manner. High arousal states are always associated with some conscious state—a percept, thought, or memory—that has a specific *content.* We see and hear something, remember an incident, plan the future, or fantasize about sex. Indeed, it is not clear whether one can be awake without being conscious of something (with the possible exception of certain meditative states). Referring to such conscious states is conceptually quite distinct from referring to states of consciousness that fluctuate with different levels of arousal. Arousal can be measured behaviorally by the signal amplitude that triggers some criterion reaction (for instance, the sound level necessary to evoke an eye movement or a head turn toward the sound source).

The number of distinct conscious states is vast and encompasses every possible type of visual, auditory, visceral, olfactory, pain, vestibular, or other sensory experience; remembered or imagined experiences; events or thoughts; and emotional experiences (fear, surprise, happiness, dread, and so on).

Different levels or states of consciousness are associated with different kinds of conscious experiences. The normal, waking state is quite different from the dreaming state (for instance, the latter has little or no self-reflection) or from deep sleep. In all three cases, the basic physiology of the brain is changed, affecting the space of possible conscious experiences. Physiology is also different in *altered states of consciousness*—for instance, after taking psychedelic drugs, when events often have a stronger emotional connotation than in normal life.

In some obvious but difficult to rigorously define manner, the *richness of conscious experience* increases as an individual transitions from deep sleep to drowsiness to full wakefulness. This richness of possible conscious experience could be quantified using notions from complexity theory that incorporate both the dimensionality as well as the granularity of conscious experience (e.g., Tononi, 2008). For example, inactivating all of the visual cortex in an otherwise normal individual would significantly reduce the dimensionality of conscious experience, since no color, shape, motion, texture, or depth could be perceived or imagined. As behavioral arousal increases, so does the range and complexity of behaviors that an individual is capable of. A singular exception to this progression is REM sleep where most motor activity is shut down in the *atonia* that is characteristic of this phase of sleep, and the subject is difficult to wake up. Yet this low level of behavioral arousal goes, paradoxically, hand in hand with high metabolic and electrical brain activity and conscious, vivid states.

These observations suggest a two-dimensional graph (Fig. 51.1) in which the richness of conscious experience (its representational capacity) is plotted as a function of levels of behavioral arousal or responsiveness.

Global disorders of consciousness can likewise be mapped onto this plane. Clinicians speak of impaired states of consciousness as in "the comatose state," "the vegetative state" (VS), and the "minimal conscious state" (MCS). Here, *state* refers to different levels of consciousness, from a total absence in the case of coma, VS, or general anesthesia, to a fluctuating and limited form of conscious sensation in MCS, sleepwalking, or during a complex partial epileptic seizure (Laureys, 2005; Schiff, 2010).

The repertoire of distinct conscious states or experiences that are accessible to a patient in MCS is presumably minimal (possibly including pain, discomfort, and sporadic sensory percepts), immeasurably smaller than the possible conscious states that can be experienced by a healthy brain. In the limit of brain death, the origin of this space has been reached with no experience at all (Fig. 51.1). More relevant to clinical practice is the case of global anesthesia, during which the patient should not experience anything so as to avoid traumatic memories and their undesirable sequelae.

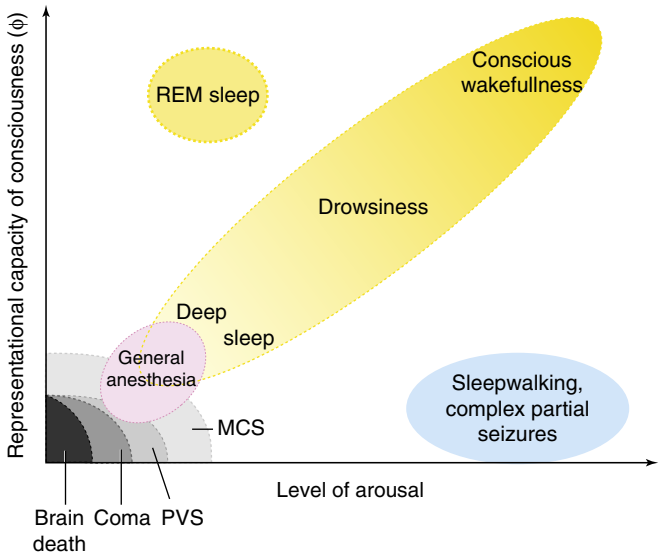

FIGURE 51.1 Normal and pathological brain states can be situated in a two-dimensional graph. Increasing levels of behaviorally determined arousal are plotted on the *x*-axis and the "richness" or "representational capacity of consciousness" is plotted on the *y*-axis. Increasing arousal can be measured by the threshold to obtain some specific behavior (for instance, spatial orientation to a sound). Healthy subjects cycle during a 24-hour period from deep sleep with low arousal and very little conscious experience to increasing levels of arousal and conscious sensation. In REM sleep, low levels of behavioral arousal go hand-in-hand with vivid consciousness. Conversely, various pathologies of clinical relevance are associated with little to no conscious content. *Modified from Laureys (2005).*

Given the absence of any accepted theory for the minimal neuronal criteria necessary for consciousness, the distinction between a VS patient—who shows regular sleep-wave transitions and who may be able to move eyes or limbs or smile in a reflexive manner as in the widely publicized 2005 case of Terri Schiavo in Florida—and a MCS patient who can communicate (on occasion) in a meaningful manner (for instance, by differential eye movements) and who shows some signs of consciousness, can be difficult in a clinical setting. This drives the need for practical, bedside tests. Two empirico-computational assays being developed rely on the breakdown of cortico-cortical interconnectivity—that is, the loss of integration within the cortico-thalamic core, associated with loss of consciousness (Boly et al., 2011; Massimini et al., 2005; Rosanova et al., 2012).

An alternative is blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI). Brain imaging of patients with global disturbances of consciousness (including akinetic mutism) reveals that dysfunction in a widespread cortical network including medial and lateral prefrontal cortex and parietal associative areas is associated with a global loss of consciousness (Laureys, 2005). Monti et al. (2010) imaged brain activity in 54 patients

with disorders of consciousness to determine whether two different mental imagery tasks that involve different brain systems ("imagine playing tennis" versus "imagine navigating through your home") can be used by the patient to communicate yes or no answers to simple questions. Five of these patients with traumatic brain injuries could willfully and reliably modulate their brain activity, with two of these having no overt sign of behavioral control during clinical assessment. This shows the promise of fMRI for establishing a two-way radio link (albeit at a very low baud rate) with a subset of VS patients.

Destruction of circumscribed parts of the cerebral cortex can eliminate very specific aspects of consciousness, such as the ability to see moving stimuli or to recognize faces, without a concomitant loss of consciousness or even conscious vision in general. Yet relatively discrete bilateral injuries to midline (paramedian) subcortical structures can cause a complete loss of consciousness. These structures are therefore part of the *enabling* factors that control the level of brain arousal (as determined by metabolic or electrical activity) and that are needed for any conscious states to form. Consider the heterogeneous collection of more than 20 (on each side) nuclei in the upper brainstem (pons, midbrain, and in the posterior hypothalamus), often collectively referred to as the *reticular activating system* (Parvizi and Damasio, 2001). These nuclei—three-dimensional collections of neurons with their own cytoarchitecture and neurochemical identity—release distinct neuromodulators such as acetylcholine, noradrenaline/norepinephrine, serotonin, histamine, and orexin/hypocretin. They can widely influence the cortex through direct axonal projections (Fig. 51.2) or via intermediary relays in the thalamus (below) and in the basal forebrain. These neuromodulators mediate the alternation between wakefulness and sleep, as well as the general level of both behavioral and brain arousal. Acute lesions in the reticular activating system can result in loss of consciousness and coma. However, eventually the excitability of thalamus and forebrain can recover and consciousness can return (Villablanca, 2004).

Another enabling factor for consciousness is the five or more *intralaminar nuclei of the thalamus* (ILN). These receive input from many brainstem nuclei and from frontal cortex and project strongly to the basal ganglia and, in a more distributed manner, into layer I of much of neocortex. Comparatively small (1 cm^3 or less) bilateral lesions in the ILN can completely eliminate awareness (Bogen, 1995). Thus, the ILN are necessary for the state of consciousness but do not appear to be responsible for mediating specific conscious percepts or memories.

If a single substance is critical for consciousness, then acetylcholine is the most likely candidate. Two

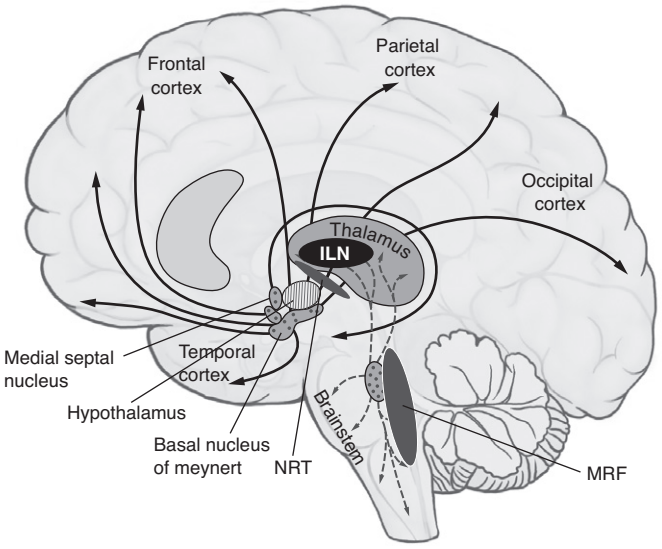

FIGURE 51.2 Midline structures in the brainstem and thalamus necessary to regulate the level of brain arousal include the intralaminar nuclei of the thalamus (ILN), the thalamic reticular nucleus (NRT) encapsulating the dorsal thalamus, and the midbrain reticular formation (MRF) that includes the reticular activating system. Small, bilateral lesions in many of these nuclei cause a global loss of consciousness.

major cholinergic pathways originate in the brainstem and in the basal forebrain (Fig. 51.2). Brainstem cells send an ascending projection to the thalamus, where release of acetylcholine facilitates thalamo-cortical relay cells and suppresses inhibitory interneurons. Cholinergic cells are therefore well positioned to influence all of the cortex by controlling the thalamus. In contrast, cholinergic basal forebrain neurons send their axons to a wide array of target structures. Collectively, brainstem and basal forebrain cholinergic cells innervate the thalamus, hippocampus, amygdala, and neocortex.

Cholinergic activity fluctuates with the sleep-wake cycle. In general, increasing levels of spiking activity in cholinergic neurons are associated with wakefulness or REM sleep, while decreasing levels occur during non-REM or slow-wave sleep. Lastly, many neurological pathologies whose symptoms include disturbances of consciousness, such as Parkinson's disease, Alzheimer's disease, and other forms of dementia, are associated with a selective loss of cholinergic neurons.

In summary, a plethora of nuclei with distinct chemical signatures in the thalamus, midbrain, and pons must function for the brain of an individual to be sufficiently aroused to experience anything at all. These nuclei belong to the enabling factors for consciousness. It is likely that the specific content of any one conscious sensation is mediated by neurons in cortex and their associated satellite structures, including the amygdala, thalamus, claustrum, and the basal ganglia.

THE NEURONAL CORRELATES OF CONSCIOUSNESS

Progress in addressing the mind-body problem has come from focusing on empirically accessible questions rather than on eristic philosophical arguments with no clear resolution. One key objective has been to search for the neuronal correlates—and ultimately the causes—of consciousness. As defined by Crick and Koch (2003), the neuronal correlates of consciousness (NCC) are the *minimal neuronal mechanisms jointly sufficient for any one specific conscious percept* (Fig. 51.3).

This definition of the NCC stresses the word "minimal" because the question of interest is which subcomponents of the brain are actually needed. For example, of the 86 billion neurons in the human brain, 69 billion are in the cerebellum (Herculano-Houzel, 2009). That is, about four out of every five brain cells are small cerebellar granule neurons. Yet the main deficits of people born without a cerebellum—a rare occurrence—or that lose part of the cerebellum to stroke or other trauma are ataxia, slurred speech, and unsteady gait (Lemon & Edgley, 2010). Thus, the cerebellum is not part of the NCC. That is, trains of spikes in granule cells—or their absence—do not contribute in any substantive way to conscious states.

This definition does not focus on the necessary conditions for consciousness because of the great redundancy and parallelism found in neurobiological networks. While activity in some population of neurons may underpin a percept in one case, a different population might mediate a related percept if the former population is lost or inactivated.

Every phenomenal, subjective state will have associated NCC: one for seeing a red patch, another one for seeing grandmother, yet a third one for hearing a siren, and so on. Perturbing or inactivating the NCC for any one specific conscious experience will affect the percept or cause it to disappear. If the NCC could be induced artificially—for instance, by optogenetics or by cortical microstimulation—the subject would experience the associated percept.

What characterizes the NCC? What are the communalities between the NCC for seeing and for hearing? Will the NCC involve all pyramidal neurons in cortex at any given point in time? Or only a subset of long-range pyramidal cells in frontal lobes that project to the sensory cortices in the back? Only layer 5 cortical cells? Neurons that fire in a rhythmic manner? Neurons that fire in a synchronous manner? These are some of the proposals that have been advanced over the years (Chalmers, 2000).

The vast majority of experiments concerned with the NCC refer to either electrophysiological recordings in monkeys or functional brain imaging data in humans.

It is implicitly assumed by most neurobiologists that the relevant variables giving rise to consciousness are to be found at the neuronal level, among the synaptic release or the action potentials in one or more population of cells, rather than at the molecular level. A few scholars have proposed that macroscopic quantum behaviors underlie consciousness. Of particular interest here is *entanglement*, the observation that the quantum states of multiple objects, such as two coupled electrons, may be highly correlated even though they are spatially separated, violating our intuition about locality (entanglement is also the key feature of quantum mechanics exploited in quantum computers). The role of quantum mechanics for the photons received by the eye and for the molecules of life is not controversial. But there is no evidence that any components of the nervous system—a 37° Celsius wet and warm tissue strongly coupled to its environment—display quantum entanglement (although there is evidence for quantum coherence in photosynthetic proteins at room temperature; Collini et al., 2010). And even if quantum entanglement were to occur inside individual cells, diffusion and action

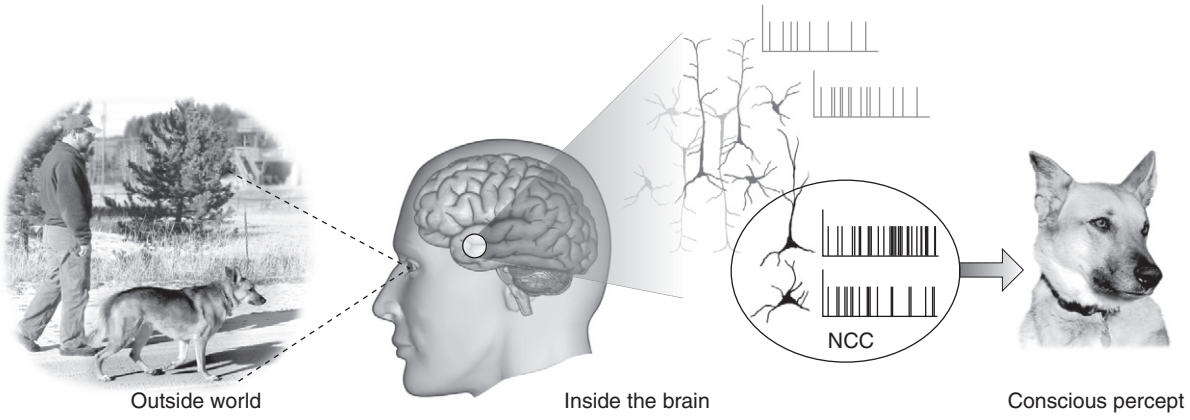

FIGURE 51.3 The **N**euronal **C**orrelates of **C**onsciousness (NCC) are the minimal set of neural events and structures—here synchronized action potentials in neocortical pyramidal neurons—sufficient for a specific conscious percept or memory. *From Koch (2004).*

potential generation and propagation—the principal mechanism for getting information into and out of neurons—would destroy superposition. At the cellular level, the interaction of neurons is governed by classical physics (Koch & Hepp, 2010).

THE NEURONAL BASIS OF PERCEPTUAL ILLUSIONS

The possibility of precisely manipulating visual percepts in time and space has made vision a preferred modality for seeking the NCC. Psychologists have perfected a number of techniques—masking, binocular rivalry, continuous flash suppression, motion-induced blindness, change blindness, inattentional blindness—in which the seemingly simple and unambiguous relationship between a physical stimulus in the world and its associated percept in the privacy of the subject's mind is disrupted (Kim & Blake, 2005). With such techniques, a stimulus can be perceptually suppressed for seconds or even minutes at a time: the image is projected into one of the observer's eyes but it is invisible, not seen. In this manner the neural mechanisms that respond to the subjective percept rather than the retinal stimulus can be isolated, permitting the footprints of visual consciousness to be tracked in the brain.

In a *perceptual illusion*, the physical stimulus remains fixed, while the percept fluctuates. One example is the *Necker cube* that can be perceived in one of two different ways in depth. Another one, that can be precisely controlled, is *binocular rivalry* (Blake & Logothetis, 2002). Here, a small image—for example, a horizontal grating—is presented to the left eye and another image—for example, a vertical grating—is shown to the corresponding location in the right eye. Despite the constant retinal stimulus, observers perceive the horizontal grating to alternate every few seconds with the vertical one. The brain does not allow for the simultaneous perception of both images.

Macaque monkeys can be trained to report whether they see the left or the right image. The distribution of the switching times and the way in which changing the contrast in one eye affects the reports leave little doubt that monkeys and humans experience the same basic phenomenon.

In a series of elegant experiments, Logothetis and colleagues (Logothetis, 1998) recorded from a variety of visual cortical areas in the awake macaque monkey while the animal performed a binocular rivalry task. In primary visual cortex (V1), only a small fraction of cells weakly modulate their response as a function of the percept of the monkey. The majority of cells responded to one or the other retinal stimulus with little regard to what the animal perceived at the time. In contrast, in a high-level cortical area such as the inferior temporal (IT) cortex along the ventral pathway, almost all neurons responded only to the perceptual dominant stimulus, that is, to the stimulus that was being reported. For example, when a face and a more abstract design were presented, one of these to each eye, a "face" cell fired only when the animal indicated by its performance that it saw the face and not the pattern presented to the other eye (Fig. 51.4). This result implies that the NCC involves activity in neurons in inferior temporal cortex.

In a related perceptual phenomena, *flash suppression*, the percept associated with an image projected into one eye is suppressed by flashing another image into the other

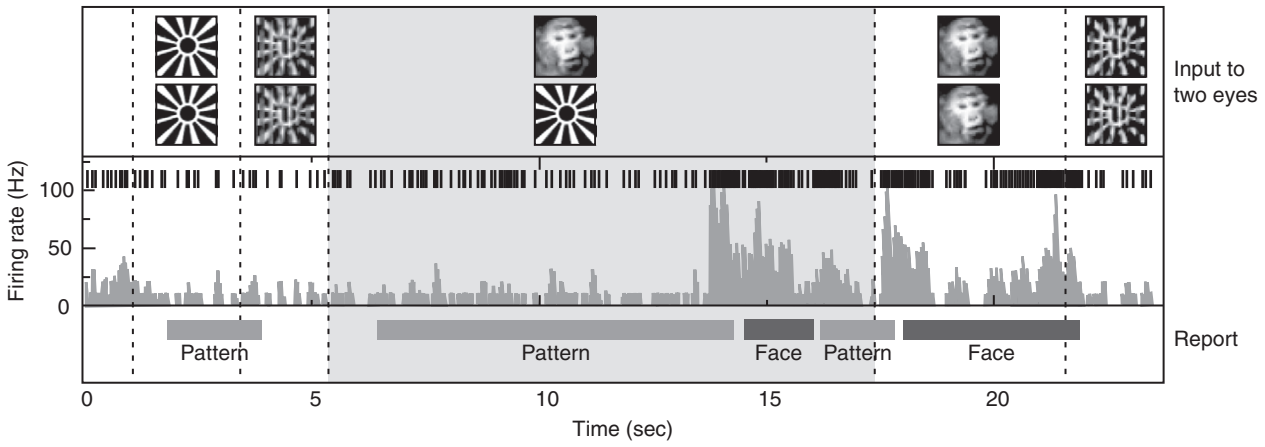

FIGURE 51.4 A fraction of a minute in the life of a typical IT cell while a monkey experiences binocular rivalry. The upper row indicates the visual input to the two eyes, with dotted vertical boundaries marking stimulus transitions. The second row shows the individual spikes, the third the smoothed firing rate, and the bottom row the monkey's behavior. The animal was taught to press a lever when it saw either one or the other image, but not both. The cell responded only weakly to either the sunburst design or to its optical superposition with the image of a monkey's face. During binocular rivalry (gray zone), the monkey's perception vacillated back and forth between seeing the face ("Face") and seeing the bursting sun ("Pattern"). Perception of the face was consistently accompanied (and preceded) by a strong increase in firing rate. *From N. Logothetis (private communication) as modified by Koch (2004).*

eye (while the original image remains). Its methodological advantage over binocular rivalry is that the timing of the perceptual transition is determined by an external trigger rather than by an internal event. The majority of responsive cells in inferior temporal cortex and in the superior temporal sulcus follow the monkey's behavior—and therefore its percept. That is, when the animal perceives a cell's preferred stimulus, the neuron fires; when the stimulus is present on the retina but is perceptually suppressed, the cell falls silent, even though legions of V1 neurons fire vigorously to the same stimulus (Sheinberg & Logothetis, 1997). Single neuron recordings in the medial temporal lobe of epileptic patients during flash suppression likewise demonstrate abolition of their responses when their preferred stimulus is present on the retina but not consciously seen by the patient (Kreiman, Fried, & Koch, 2002).

A large number of fMRI experiments have exploited binocular rivalry and related illusions to identify the hemodynamic activity underlying visual consciousness in humans. They demonstrate quite conclusively that BOLD activity in the upper stages of the ventral pathway (e.g., the fusiform face area and the parahippocampal place area) follow the percept and not the retinal stimulus (Rees & Frith, 2007).

There is a lively debate about the extent to which neurons in primary visual cortex simply encode the visual stimulus or are directly responsible for expressing the subject's conscious percept. That is, is V1 part of the NCC (Crick & Koch, 1995)? It is clear that retinal neurons are not part of the NCC for visual experiences. While retinal neurons often correlate with visual experience, the spiking activity of retinal ganglion cells does not accord with visual experience (for example, there are no photoreceptors at the blind spot; yet no hole in the field of view is apparent; in dreams vivid imagery occurs despite closed eyes and so on). A number of compelling observations link perception with fMRI BOLD activity in human V1 and even LGN (Lee, Blake, & Heeger, 2005; Tong, Nakayama, Vaughan, & Kanwisher, 1998). These data are at odds with single neuron recordings from the monkey. A plausible explanation is that V1 neurons receive feedback signals during conscious perception that are not, however, sufficient to drive the cells to spike (Maier et al., 2008).

Haynes and Rees (2005) exploited multivariate decoding techniques to read out perceptually suppressed information (the orientation of a masked stimulus) from V1 BOLD activity, even though the stimulus orientation was so efficiently masked that subjects performed at chance levels when trying to guess the orientation. That is, although subjects did not give any behavioral indication that they saw the orientation of the stimulus, its slant could be predicted on a single trial basis with better than chance odds from the V1 (but not from V2 or V3) BOLD signal. This finding supports the hypothesis that information present in V1 is not accessible to visual consciousness.

What all of these experiments demonstrate is that the neuronal basis of consciously experienced perceptions can be identified and studied using standard neuroscience tools.

PERCEPTUAL PUZZLES OF CONTEMPORARY INTEREST

The attributes of even simple percepts vary along a continuum. For instance, a patch of color has a brightness and a hue that are variable, just as a simple tone has an associated loudness and pitch. However, is it possible that each particular, consciously experienced, percept is all-or-none? Might a pure tone of a particular pitch and loudness be experienced as an atom of perception, either heard or not, rather than gradually emerging from the noisy background? The perception of the world around us would then be a superposition of many elementary, binary percepts (Sergent & Dehaene, 2004).

Is perception continuous, like a river, or does it consist of a series of discontinuous batches, rather like the discrete frames in a movie (Purves, Paydarfar, & Andrews, 1996; VanRullen & Koch, 2003a). In *cinematographic vision* (Sacks, 2004), a rare form of visual migraine, the subject sees the movement of objects as fractured in time, as a succession of different configurations and positions, without any movement in between. The hypothesis that visual perception is quantized in discrete batches of variable duration, most often related to EEG rhythms in various frequency ranges (from theta to beta), is an old one. This idea is being revisited in light of the discrepancies of timing of perceptual events within and across different sensory modalities. For instance, even though a change in the color of an object occurs simultaneous with a change in its direction of motion, it may not be perceived that way (Bartels & Zeki, 2006; Stetson, Cui, Montague, & Eagleman, 2006),

What is the relationship between endogenous, top-down attention and consciousness? Although these are frequently coextensive—subjects are usually conscious of what they attend to—there is considerable evidence that argues that these are distinct neurobiological processes (Koch & Tsuchiya, 2007). This question is receiving renewed "attention" due to the development of a powerful visual masking technique that can suppress stimuli for minutes at end (*continuous flash suppression*; Tsuchiya & Koch, 2005). Indeed, it has been shown that attention can be allocated to a perceptually invisible stimulus (Naccache, Blandin, & Dehaene, 2002; for a review of many of these experiments see van Boxtel, Tsuchiya, & Koch, 2010a).

That is, subjects can pay attention to something without seeing what they are paying attention to! In other experiments, visual attention has an opposing effect on afterimage duration than visual consciousness (van Boxtel, Tsuchiya, & Koch, 2010b; Watanabe et al., 2011), dissociate selective, visual attention and consciousness—as assayed via stimulus visibility—in human primary visual cortex. Whether or not subjects see what they are looking at makes very little difference to the hemodynamic signal in V1, while attention strongly modulates the BOLD response. When exploring the neural basis of these processes, it is therefore critical to not confound consciousness with attention. Whether the converse also occurs—being conscious of something without attending to it—remains an open question.

FORWARD VERSUS FEEDBACK PROJECTIONS

Many actions in response to sensory inputs are fast, transient, with a limited behavioral repertoire, and unconscious (Milner & Goodale, 1995). Part of the habit system that controls automatic behavior (Shiffrin & Schneider, 1977), these behaviors can be thought of as cortical reflexes. They are characterized by rapid and stereotyped sensory-motor actions called *zombie behaviors* (Koch & Crick, 2001). Examples include eye and hand movements; limb adjustments; keyboard typing; driving a bicycle; executing well-rehearsed sequences in tennis, soccer, or any other athletic activity; and so on. Such automatic behaviors are complemented by a nonhabit, slower, all-purpose conscious mode that deals with more complex aspects of the sensory input (or a reflection of these, as in imagery) and takes time to decide on appropriate responses. A consciousness mode is needed because otherwise a vast number of different zombie modes would be required to react to unusual events. The conscious system may interfere somewhat with the concurrent zombie systems (Logan & Crump, 2009): focusing consciousness onto the smooth execution of a complex, rapid, and highly trained sensory-motor task—dribbling a soccer ball or typing on a keyboard—can interfere with its smooth execution, something well known to athletes and their trainers. Having both a zombie mode that responds in a well-rehearsed and stereotyped manner as well as a slower system that allows time for thinking and planning more complex behavior is a great evolutionary discovery. This latter aspect, planning, may be one of the principal functions of consciousness.

It seems possible that visual zombie modes in the cortex mainly use the dorsal stream in the parietal region (Milner & Goodale, 1995). However, parietal activity can affect consciousness by producing attentional effects on the ventral stream, at least under some circumstances. The basis of this inference is clinical case studies and fMRI experiments in normal subjects (Corbetta & Shulman, 2002). The conscious mode for vision depends largely on the early visual areas (beyond V1) and especially on the ventral "what" stream.

Seemingly complex visual processing (such as detecting animals in natural, cluttered images) can be accomplished by cortex within 130–150 msec (Thorpe, Fize, & Marlot, 1996; VanRullen & Koch, 2003b), far too slow for conscious perception to be involved. It is plausible that such behaviors are mediated by a purely feed-forward moving wave of spiking activity that passes from the retina through V1, into V4, IT and prefrontal cortex, until it affects motorneurons in the spinal cord that control the finger press (as in a typical laboratory experiment). The hypothesis that the basic processing of information is feedforward is supported most directly by the short times required for a selective response to appear in IT cells (Perrett et al., 1992). Indeed, Hung, Kreiman, Poggio, and DiCarlo (2005) were able to decode from the spiking activity of a couple of hundred neurons in monkey IT (over intervals as short as 12.5 msec and about 100 msec after image onset) the category, identity, and even position of a single image flashed onto the retina of the fixating animal. Coupled with a suitable motor output, such a feed-forward network implements a zombie behavior in the Koch and Crick (2001) sense—rapidly and efficiently subserving one task, here distinguishing animal from nonanimal pictures, in the absence of any conscious experience.

Conscious perception requires more sustained, reverberatory neural activity, most likely via global feedback from frontal regions of neocortex back to sensory cortical areas in the back (Crick & Koch, 1995; Lamme & Roelfsema, 2000; Fahrenfort, Scholte, & Lamme, 2008). Such feedback loops would explain why in backward masking a second stimulus, flashed 80–100 msec after onset of a first image, can still interfere with (mask) the percept of the first image. The reverberatory activity builds up over time until it exceeds a critical threshold. At this point, the sustained neural activity rapidly propagates to parietal, prefrontal, and anterior cingulate cortical regions; thalamus, claustrum, and related structures that support short-term memory; and multimodality integration, planning, speech, and other processes intimately related to consciousness. Dehaene et al. (2001) contrasted brain activity during presentation of flashed, masked words with the activity evoked when the words were not masked (Fig. 51.5). BOLD activity in the fusiform (visual) cortex and in a spatially extended network of midline prefrontal and inferior parietal cortices tracked conscious perception.

This is the hypothesis at the heart of the *global workspace* model of consciousness (Baars, 1989; Dehaene & Changeux, 2011). Sensory information is processed in

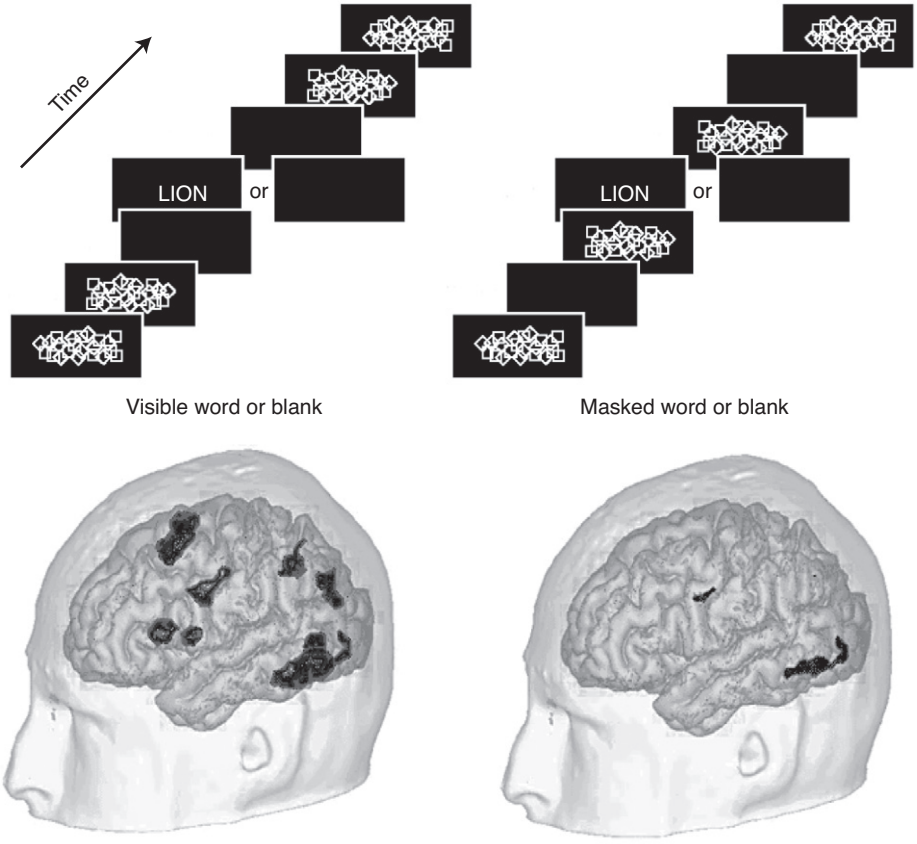

FIGURE 51.5 The Effect of Visual Masking. The brain's response to seen and unseen words. Volunteers looked at a stream of briefly flashed images. No words were seen in the right stream, since each word was preceded and followed by a slide covered by random symbols, perceptually obscuring the letters. This had a dramatic effect on the cortical fMRI response (the activity following the image sequences with words was compared to the sequences with blanks). Both seen and masked words activated regions in the left ventral pathway, but of much different amplitude. Conscious perception triggered additional widespread activation in left parietal and prefrontal cortices. *Modified from Dehaene et al. (2001).*

an array of feed-forward structures, such as primary sensory cortices. If it is powerful enough, it enters into a *global neuronal workspace* located in prefrontal cortical structures. From there it is widely broadcast by long-range cortico-cortical projections and placed into context—for instance, by accessing memory and planning systems. This interpretation feeds back to the sensory representation in visual cortex. Competition inside the global neuronal workspace prevents more than one or a very small number of percepts to be simultaneously and actively represented.

In summary, while rapid but transient neural activity in the thalamo-cortical system can mediate complex behavior without conscious sensation, it is surmised that consciousness requires sustained but well-organized neural activity dependent on integration across cortex.

One hitherto neglected structure in this regard is the claustrum. It is a thin (*ca.* 1 mm) sheet of neurons underneath the insular cortex, extending all the way into temporal, parietal, and frontal lobes, and above the putamen, buried in white matter structures. It projects to, and receives input from, perhaps all cortical regions. Crick and Koch (2005) surmised that the claustrum is critical to the integration of information underlying consciousness, akin to a conductor of the cortical orchestra.

AN INFORMATION-THEORETICAL THEORY OF CONSCIOUSNESS

At present, it is not known to what extent animals whose nervous systems have an architecture considerably different from the mammalian neocortex are conscious. Furthermore, whether artificial systems, such as computers, robots, or the World Wide Web as a whole, which behave with considerable intelligence, are or can become conscious (as widely assumed in science fiction; e.g., the paranoid computer *HAL* in the film *2001*), remains speculative (Koch and Tononi, 2011). What is needed is a theory of consciousness that explains in quantitative terms what type of systems, with what architecture, can possess conscious states.

Progress in the study of the NCC on the one hand, and of the neural correlates of nonconscious habit or zombie behaviors on the other, will hopefully lead to a better understanding of what distinguishes neural structures or processes that are associated with consciousness from those that are not. Yet such an opportunistic, data-driven approach will not lead to an understanding of why certain structures and processes have a privileged relationship with subjective experience. For example, why is it that neurons in corticothalamic circuits are essential for

conscious experience, whereas cerebellar neurons, despite their huge numbers, are not? And what is wrong with cortical zombie systems that make them unsuitable to yield subjective experience? Or why is it that consciousness wanes during slow-wave sleep early in the night, despite levels of neural firing in the thalamocortical system that are comparable to the levels of firing in wakefulness?

Information theory may be such a tool that establishes at the fundamental level what consciousness is, how it can be measured, and what requisites a physical system must satisfy in order to generate it (Chalmers, 1996; Tononi & Edelman, 1998).

The only promising candidate for such a theoretical framework is the *information integration theory of consciousness* (Tononi, 2008). It posits that consciousness is extraordinarily *informative*. Any one particular conscious state rules out a huge number of alternative experiences. Classically, the reduction of uncertainty among alternatives constitutes information. For example, when a subject consciously experiences reading this particular phrase, a huge number of other possible experiences are ruled out (consider all possible written phrases that could have been written in this space, in all possible fonts, ink colors, and sizes; think of the same phrases spoken aloud, or read and spoken, and so on). Thus, every experience represents one particular conscious state out of a huge repertoire of possible conscious states.

Furthermore, information associated with the occurrence of a conscious state is also *integrated*. Any one experience is an indivisible whole. It cannot be subdivided into components that are experienced independently. Again, the conscious experience of this particular phrase cannot be experienced as subdivided into, say, the conscious experience of nouns independently of the verbs. Similarly, visual shapes cannot be experienced independently of their color, nor can the left half of the visual field of view be experienced independently of the right half.

Based on these two considerations, the theory claims that a physical system can generate consciousness to the extent that it integrates information. This requires that the system has a large repertoire of available states (information) that cannot be decomposed into a collection of causally independent subsystems (integration).

Importantly, the theory introduces a measure of a system's capacity to integrate information. This measure, called Φ, is obtained by determining the minimum repertoire of different states that can be produced in one part of the system by perturbations of its other parts (Tononi, 2008). Φ can loosely be thought of as the representational capacity of the system (as in Fig. 51.1). Although Φ is not easy to calculate exactly for realistic systems (Balduzzi & Tononi, 2008), it can be estimated. Thus, by using simple computer simulations, it is possible to show that Φ is high for neural architectures that conjoin functional specialization with functional integration, like the mammalian thalamocortical system. Conversely, Φ is low for systems that are made up of small, quasi-independent modules, like the cerebellum, or for networks of randomly or uniformly connected units.

The notion that consciousness has to do with the brain's ability to integrate information has been tested directly by transcranial magnetic stimulation (TMS). A coil is placed above the skull, and a brief and intense magnetic field generates a weak electrical current in the gray matter underlying the skull. Massimini et al. (2005) compared multichannel EEG of awake and conscious subjects in response to TMS pulses to the EEG when the same subjects were deeply asleep—a time during which consciousness is much reduced. During quiet wakefulness, an initial response at the stimulation site was followed by a sequence of waves that moved to connected cortical areas several centimeters away. During slow-wave sleep, by contrast, the initial response was stronger but was rapidly extinguished and did not propagate beyond the stimulation site. Thus, the fading of consciousness during certain stages of sleep, as well as during anesthesia (Alkire, Hudetz, & Tononi, 2008) and during loss of consciousness in patients (Rosanova et al., 2012), may be related, as predicted by the theory, to the breakdown of information integration among specialized thalamocortical modules.

CONCLUSION

Ever since the Greeks first considered the mind-body problem more than two millennia ago, it has been the domain of armchair speculations and esoteric debates with no apparent resolution. Yet many aspects of this ancient set of questions now fall squarely within the domain of science.

In order to advance the resolution of these and similar questions, it will be imperative to record from a large number of neurons simultaneously at many locations throughout the cortico-thalamo system and related satellites in people or behaving animals, such as monkeys or mice. Progress in understanding the circuitry of consciousness therefore demands a battery of behaviors (akin to but different from the well-known Turing test for intelligence) that the subject—a newborn infant, immobilized patient, monkey, or mouse—has to pass before considering him, her, or it to possess some measure of conscious perception. This is not an insurmountable step for mammals such as the monkey or the mouse that share many behaviors and brain structures with humans. For example, one particular mouse model of contingency awareness (Han et al., 2003) is based on the differential requirement for awareness of trace versus delay associative eyeblink conditioning in humans (Clark & Squire, 1998).

The growing ability of neuroscientists to manipulate in a reversible, transient, deliberate, and delicate manner

genetically identified populations of neurons using methods from molecular biology (Gradinaru, Mogri, Thompson, Henderson, & Deisseroth, 2009; Lin et al., 2011) opens the possibility of moving from correlation—observing that a particular conscious state is associated with some neural or hemodynamic activity—to causation. Exploiting these increasingly powerful tools depends on the simultaneous development of appropriate behavioral assays and model organisms amenable to large-scale genomic analysis and manipulation, particularly in mice (Lein et al., 2007). For example, if the masking experiment of Dehaene and colleagues (Fig. 51.5) is repeated using appropriately adjusted parameters in the mouse's visual system, all cortico-cortical feedback can be transiently inactivated to test to what extent this massive and sustained activity that in humans is associated with conscious perception depends on top-down connections.

It is the combination of such fine-grained neuronal analysis in mice and monkeys, ever more sensitive psychophysical and brain imaging techniques in patients and healthy individuals, and the development of a robust theoretical framework that lend hope to the belief that human ingenuity can, ultimately, understand in a rational manner one of the central mysteries of life.

Translocon-associated protein (TRAP), *67*
Treadmilling, 374
TRH, *see* Thyrotropin-releasing hormone
Tricarboxylic acid cycle (TCA), *263*, 269
Trigeminal system, somatosensory system, *548–549*
Triglyceride, 768
Tripartite junctions, *395*
Triplet repeat diseases, *936–937*
TrkC receptor, 397
Trophic factors, and programmed cell death, 431–434
TRP, *see* Transient receptor potential
Trunk neural crest cells, *345*
TS, *see* Tourette syndrome
TSH, *see* Thyroid-stimulating hormone
TTX, *see* Tetrodotoxin
Tuberomammilary nucleus (TMN), 851
Tubulin, posttranslational modification, *77*
Tuning curve, *505*
Two-photon glutamate uncaging, *243*
Two-tone suppression, 564
Tyrosine hydroxylase (TH), catecholamine biosynthesis, 120–122

U

Ultradian patterns, neurohormone release, 802–803
Unconditioned response (UR), 1010
Unconditioned stimulus (US), 1009, *1010*
Unconventional transmitters, 132–136
Unipolar brush cell, *682*, 683
Utricle, vestibular apparatus, 632
Utrophin, 392–393

V

VAChT, *see* Vesicular cholinergic transporter
Vagal neural crest cells, *344*
Vagotomy, 770
Vascular endothelial growth factor A (VEGFA), 373
Vascular organ of the lamina terminalis (OVLT), 721, *722*, 725–726
osmoreceptor cells, 787–789
Vasoactive intestinal peptide (VIP), 821, *838*
Vasoactive intestinal polypeptide (VIP), and sleep control, 858
Vasopressin, *see* Arginine vasopressin
Venous sinus, 37
Ventilation, experimental analysis of, *751*
Ventral caudal, somatosensory system, 540
Ventral intraparietal area (VIP), and spatial cognition, 974–975
Ventral organizers, DV axis, 302–303
Ventral pathway, 1063
Ventral processing streams, 959, *960*
Ventral respiratory column (VRC), 751, *752*
Ventral respiratory group (VRG), 751
Ventral system, of basal ganglia, *670*
Ventral tegmental area (VTA), *670*
Ventrolateral hypothalamus (VLH), 776
Ventrolateral preoptic area (VLPO), control of sleep-wake cycles, 852
Ventromedial hypothalamus (VMH), *773*, 776
Ventroposteromedial nucleus of the thalamus (VPMpc), taste processing, 519
Vergence eye movement, 699
Versional eye movement, 699
Vertebral artery, 36
Vertebrate hindbrain, 296
Vesicle docking, 152–153
Vesicular cholinergic transporter (VAChT), 127
Vesicular monoamine transporter (VMAT), 122–123
Vestibular canals, and otoliths, *633*
Vestibular nuclei (VN), 689, *707*
Vestibular system
apparatus, 632–633
balance and context-dependent postural strategies, 636
damage and postural disorders, 636–637
neurons in, 633–634
plasticity, *637*
vestibular and reticular nuclei, 631–633
vestibulocervical and vestibulospinal reflexes, 634–635
Vestibulo-ocular reflex (VOR), 697
gaze stabilization, 703–704
VIP, *see* Vasoactive intestinal peptide; Vasoactive intestinal polypeptide; Ventral intraparietal area
Visceral afferents, 740–743
Visceral motor pattern, *730*, *732*
Vision, 577, *see also* Eye, Object recognition, Spatial cognition
color vision defects, *584*
color-selective response in P pathway, 585–586
development of visual system, 923–924
dorsal visual stream and spatial attention, 924
ventral visual stream and object representation, 924
eye, 579–580
M cells and contrast sensitivity, 586
photoreceptors, 581
receptive fields, 577

response properties of P an M pathways, 584–585
retina structure and cells, 580–581
retinal ganglion cell, *see* Retinal ganglion cell
retinogeniculocortical pathway
extrastriate visual areas, 592–593
lateral geniculate nucleus structure, 586–587
parietal cortex, 593–594
primary visual cortex
cat, 587–589
macaque, 589
visual cortex
columnar structure, 589–590
cytochrome oxidase staining, 592
optical imaging studies, 590–592
visuomotor coordination and reaction time, 608–611
Visual agnosia, 948–949
associative, *948*, 949–950, *950*
invariant object representations, 949–950
Visual cortex
experience effects on functional organization, 487
critical period, 487–489
plasticity mechanisms, 488–489
neural activation, 992–994, *992–993*
synapse elimination, 448–451
Visual masking, effect of, *1100*
Visual search paradigm, 1001
Visuospatial cognition, 970, 974, *978*
VLH, *see* Ventrolateral hypothalamus
VLPO, *see* Ventrolateral preoptic area
VMAT, *see* Vesicular monoamine transporter
VMH, *see* Ventromedial hypothalamus
VN, *see* Vestibular nuclei
VNO, *see* Vomeronasal organ
Vocal learning, *481*, 482–483
Voltage-clamp, principles, *103*
Voltage-gated calcium channels (VGCCs), *397*, 1018, *1019*, 1020
Voltage-gated channels
immunostaining, 242
nonuniform expression, 244
Volume homeostasis, *see* Fluid intake
Vomeronasal organ (VNO), 527–528
signal transduction, 528
TRPC2, 528
VOR, *see* Vestibulo-ocular reflex
VPMpc, *see* Ventroposteromedial nucleus of the thalamus
VRC, *see* Ventral respiratory column

W

Waking, and reticular formation, 851–852
Warts, dendrite development role in *Drosophila*, 460
WASP, *see* Wiskott–Aldrich syndrome protein
Water channels, *786*
Water intake, *see* Fluid intake
Water intoxication, *791*
Weakly excitable dendrites
backpropagating action potentials, *241*, 242
dendritic recordings, 241, *241*
soma and, 240
Weather prediction task, *1042*
Werdnig–Hoffman disease, *622*
Wernicke's area, *1060*
White matter
developmental changes, 922
spinal cord, *26*, 33
Wisconsin card sorting test (WCST), 939, 1072, 1074–1077
Wiskott–Aldrich syndrome protein (WASP), 352
Wnt
dendrite growth and branching regulation, 462
growth cone guidance, 372
Word recognition, 1062–1064
Working memory, 1074, 1083–1084

X

X cells, *582*
